Regional Diagnosis

1

DESCRIPTIVE TERMS

Diagnosis is the art and the science of recognizing the presence or the absence of disease from signs, symptoms or laboratory data, of determining its character and assigning a name thereto. The assignment of the name to a disease often but not always connotes knowledge of the causal factors of the disease; that its character has been determined with reference to type and severity; an estimation of the amount and kind of damage, both general and local, which the patient has received; forecast of the probable course and duration of the morbid process; and cognizance of the personal characteristics of the patient, whether psychic or physical, inherited or acquired.

Purpose of Descriptive Terms. In both the art and the science of diagnosis there are certain descriptive terms of accepted usage, some of historic interest, and others of practical value and convenience, which are used to qualify *diagnosis* and *symptoms* respectively, as now will be shown.

Diagnostic Terms *Anatomic:* based on definite anatomic alterations on which the phenomena depend, a postmortem diagnosis.

Clinical based on the symptoms manifested during life

By Exclusion reached by a deductive process, all the affections which present salient points of similarity with the one to be diagnosed being reviewed in turn, and each successively discarded as one or more of its essential features are missed in a given case, until but one possibility remains, which is accepted as the true one.

Differential the process of distinguishing between different diseases which resemble one another.

Direct: the symptoms are of such a nature that they point to the presence of one special disease and are not capable of misinterpretation.

Pathologic of the nature of a lesion, without regard to its situation. Biopsy: in pathologic diagnosis, usage has established that microscopic examination of living tissue has largely superseded anatomic or postmortem diagnosis.

Physical. by means of physical (objective) signs, irrespective of subjective symptoms, as, for example, by palpation and auscultation.

Presumptive. not regarded as certain.

Retrospective of some antecedent disease or injury, the nature of which can be deduced only from the history given and from the persistent effects

Symptomatic. consisting simply in the determination of the most striking symptoms

Topographic: of the seat of a lesion.

Symptomatic Terms. *Constitutional or General* those that may result from unbalancing of the body as a whole, and are common to diseases of many kinds, especially the severe infections, allergies, and the endocrine and metabolic disorders

Direct those depending directly on the disease.

Local. those which result from localized disease and are usually confined to the site of the diseased organ or tissue

Pathognomonic. those which undeniably indicate the existence of a certain disease.

Reflex those which are caused by local disease, but manifest themselves by means of the nervous system in an otherwise unrelated organ or part of the body

Sympathetic those which appear with the essential ones, but for the presence of which no cause can be assigned except that of sympathy

The Normal (Normal Limits). The term normal as applied to the human b involves an easy assumption of accuracy often entirely unjustified by the facts. well to be cognizant that the use of this term implies a whole series of are known but not expressed For instance, if the expression normal in in reference to an individual, it means that the expositor is aware of the fac many persons differ even from an average mean size of their own race, and fr the members of their own families, and still are within a range of normal size

The anatomic range of the size and shape of the body as a whole is well del ated for each race. Within each race men, women and children can be separa into groups having certain somatic conformations When an individual is found a race who cannot be placed within one of these somatic groups, that individua abnormal for that particular race However, if adjudged by the standards of anotl race, this abnormal individual could become an individual with normal standa for body type For example, a white man or a Negro the size of a normal pyg would, in the United States, be considered abnormal—a dwarf, whereas if amo pygmies, he would be of normal size

Variation in the human body is inherent in all races A good example is afford by the measurements of the female pelvis. One of every 9 white women examin has a generally contracted pelvis. Application of these same measurements to Neg women reveals that 1 of every 3 has a generally contracted pelvis Obstetric expe ence teaches that the generally smaller, contracted pelves, according to the measur ments for white women, may be normal for Negro women The smaller and soft heads of Negro babies pass through these smaller pelves without difficulty

The physician of experience realizes that in order to express a normal or health or qualitative arrangement it is necessary to recognize the average which applies i most instances and the factors which may cause variations from the average. H knows that these factors may cause variations above and below average in particula instances which must still be considered the usual

Two persons of the same race, age and sex may be of the same height, withi the limits of normal as prescribed by height-weight standards, but may have differen body weights. The body weight of one may exceed the specified normal, and the body weight of the other may be less than the normal An experienced physician will appraise the overweight person If the weight exceeds the accepted normal because of excessive body musculature, the individual is accepted as being normal; if the body weight is due to excessive fat, he or she is warned of the excessive weight. The physician likewise will appraise the body weight of the underweight person, if he is convinced that the underweight person eats and sleeps well and suffers no unusual fatigue, he will accept this individual as being within the limits of normal However, if he finds that the underweight person suffers easy fatigue, sleeps poorly and does not eat well, he will attempt to elucidate the reasons for such behavior and will make appropriate recommendations for a betterment of the patient's health

The person who is underweight for the height is often of a particular somatic type, the visceroptotic Many persons of this type are tall and have but little subcutaneous and abdominal fat, so that the skin of the body and abdominal organs sag Formerly persons of this type were considered abnormal The sagging abdominal viscera were upheld by expensive abdominal supports or were subjected to extensive surgical operations to correct the splanchnoptosis Since the visceroptotic type falls within the limits of the normal, neither of these therapeutic procedures benefited the patients. The patients may be returned to health by some gain in weight

Organs and structures have a range of normal variation in size, shape and position. Throughout this text certain measurements for size, shape and position for organs will be given. It is realized that these descriptions merely approach accuracy However, it is better to have an idea of what approaches the normal limits of the size, shape and position of an organ than no idea at all

The range of variation in size, shape and position of an organ depends on many factors, but often on the size and shape of the body as a whole or on aberrations in development and in the range of natural variation. The aberrations in development usually follow certain patterns which can be deduced by a review of the developmental history during intra-uterine life or can be deduced from the history of particular diseases or trauma.

Where bodily function is concerned, a sharp differentiation between inborn variations of health and induced variations of disease or a demarcation between normal and abnormal is not immediately possible. A structure or function showing an extreme degree of variation from the mean may contribute to certain predispositions to disease or injury. The tall man is more likely than the short man to hurt his head when passing through a doorway. Someone who has hyperchlorhydria and a rapidly emptying stomach is more likely under stress and strain to contract or retain a duodenal ulcer than someone who has a less active organ and low gastric acidity. A man who has had a slight stenosis at the neck of the bladder all of his life may begin to have symptoms of prostatism when the prostate becomes insignificantly enlarged at the age of 40 or 45 years. A girl who has had pyelitis during childhood may cease to have any symptoms referable to the urinary tract until her honeymoon or until her first pregnancy. The normals and abnormals in those who have inborn variations of health and induced variations from disease may become differentiable after disease has become established.

The chief difficulties in clinical interpretations are encountered at the extreme ranges of natural variation Variability of one individual from another and variability influenced by age, sex and activity in a species are essential to survival. However, a complete standardization of structure and function would be incompatible with survival. These are statements which refer to the extremes In clinical diagnosis the concern is with the deviations from the usual structure and functions which are indicative of disease. For instance, it cannot be said at exactly what point the pulse ... t what point the heart sounds, the breath sounds, the ... the knee jerk or the ankle jerk, the size and charac- ... ate of the thyroid pass from normality to the stage of disease.

The pulse rate, the blood pressure, the body temperature, the total and differential leukocyte counts, the erythrocyte counts, the concentrations of glucose and urea in the blood, and the basal metabolism are examples of normal range. Single determinations of these phenomena which have a normal range may not be significant in ... n what place ... disease. For ... ml. of blood may lose through hemorrhage a considerable amount of blood, and still the hemoglobin concentration remains within the range of normal. It is the trend of these values established by repeated determinations that is significant in the diagnosis of the normal state or the state of disease. Consequently, the dictionary definition of normal is not the same as when the term is employed by physicians in reference to the human body.

The range of human physiologic and psychologic normality has always been difficult to determine In many physiologic functions statistical methods have been employed. For instance, Ivy says that "a function of the body is statistically normal or usual when its value falls within the central 68 26 per cent of the values found in the same species, race, age and sex " The 68 per cent value is chosen because persons with high and low values of function and without the symptoms of disease are regarded with suspicion. They should not be called abnormal, however, unless other functions and margins of safety can actually be shown to be interfered with or reduced.

and growth are easily confused The growth of a single person may be physiolo normal, though statistically abnormal Slow or rapid growth revealed by the tical method may be suspected of being physiologically abnormal but cannot be sidered abnormal until a cause is found The same is true with aging

Throughout this text attempts will be made, within bounds, to define the n anatomic or physical limits of many important structures The source of such mation has been my own experience and standard textbooks on anatomy but cipally Davis' *Applied Anatomy* and the American edition of Gray's *Anatomy*.

In some instances the physiologic limits of normal will be given. However physiologic limits of normality are often difficult to ascertain, and when data given on physiologic limits of normality these data have been obtained from s of animals not closely akin to man Likewise when there are known definite pa logic changes characteristic of a disease, the gross changes will be stated. More ra will microscopic characteristics be emphasized and then for special reasons.

THE COMPLAINT AND THE HISTORY

THE COMPLAINT

The term complaint may be used in one meaning only; or it may be employed another meaning only. Often the term is used in different senses at different times without definition. The term admissibly means one of the following: (1) the description of the difficulties which the patient relates to the physician, (2) the symptom or symptoms which cause the patient to visit the physician, (3) the disease or diseases which underlie the symptom or symptoms which cause the patient to visit the physician. Most properly the term seems to mean the first of the three, and so shall it be used in the following discussion

In the clinical record, in order better to elaborate the history, an attempt is made to enumerate the complaints as they are given Some patients will complain of 5 or 10 or more disabilities. Actually, at times, all of these complaints will refer to only one disease. It is usual for the patient who has a functional disorder to make multiple complaints An enumeration of complaints is often diagnostically valuable because such an enumeration will permit of the detection of a disease if present, and also of the functional overlay of symptoms which may be present

The complaint is expressed chiefly by spoken words. Often the words are emphasized by signs, symbols, acts or motions, and under the stress of emotions and pain or profound psychic tension all may not make sense, frequently, therefore, the physician finds himself separated from the complainer because of inability to understand what the complainer means.

In social or business intercourse the formal and polished language of the educated person is a most desirable asset. In the expression of a clinical complaint, however, misplaced elegant words, fine but vague terms, can be at times as disastrous as meaningless words and physical acts. In eliciting the complaint, one should lead the patient to use words that he understands It is the physician's task to understand the patient. In these communications education on the part of the patient is not essential If at all possible, however, intelligent comprehension by the patient of the physician's interrogations is essential. Therefore under all circumstances words must be used, the meaning of which the patient understands The physician must think with the patient and try to understand what the patient wishes to communicate to him It is well to recall that when misused, "words, words, words, are the stumbling blocks in the way of truth. Until you think of things as they are, and not of the words that misrepresent them, you cannot think rightly. Words produce the appearance of hard and fast lines where there are none. . . . Words are the clothes that thoughts wear—only the clothes. I say this over and over again, for there is nothing of more importance. . . . If I could *think* to you without words you would understand me better" (Excerpt, with omissions, from *Anonymous,* quoted by Samuel Butler in *Life and Habit.*)

To follow through with an adaptation from Malinowski: The complaint of a patient is never detached from the situation in which it has been uttered. For each complaint by a human being there is the aim and function of expressing some ...ling actual at that moment and in that situation, and necessary for

some reason or other to be made known to the physician in order either to purposes of common action, or to establish ties which will serve the purpc communion, or else to deliver the complainer of violent feelings or passions. out some imperative stimulus of the moment, there can be no spoken complai each case, therefore, utterance and situation are bound up inextricably with other and the context of situation is indispensable for the understanding of the v Exactly as in the reality of spoken or written languages, a word *without ling context* is a mere figment and stands for nothing by itself, so in the reality spoken living tongue, the utterance has no meaning except in the context of situ

In eliciting the complaint, the simplest, the most natural and, in the en almost self-evident facts are the hardest to evolve and to elucidate and the most cult to interpret. Complaints referring to the primitive fundamental instincts o preservation and reproduction must be carefully listened to, for it is these ins which are so important because they have served to guide mankind in the forn of religious and ethnic systems of moral and spiritual guidance. Often comp are tainted with folkway and folk medicine. Folkway and folk medicine are tially al[illegible]

Every complaint presents at least two components (1) the amount of ph disability present, and (2) the reactions of the nervous system to this disabil in sc

of interrogation
it is unnecessary to question and cross-examine the patient and members c family or friends. Elucidation of many complaints, however, requires though consideration. There are, too, those complaints, apparently definite, whicl patient states clearly and precisely, but which on cross-examination fail to be c significance except to the patient.

Diligence, working theories and hypotheses are occasionally necessary task of eliciting data for a starting point in ascertaining what a patient means complains, "I feel bad all over," who steadfastly maintains this contentior answers normally and satisfactorily all questions pertaining to either the psyc the soma

Complaints can often be separated into those which are purely psychic and those which are purely somatic in origin. Other complaints cannot be definitely classed as either purely psychic or purely somatic and are termed psychosomatic, and finally there are those complaints which are of somatic origin but often colored by the temperament of the patient. It must be emphasized that it is just as important to determine whether a patient is suffering in silence as to know that an overemphasis is being expressed.

Psychic Complaints. At this point in the search for pertinent data in regard to the complaint it is well to digress long enough to define briefly the psychic functions which often are of great importance in the interpretation of the complaint and particularly of complaints which are partially or wholly of psychic origin.

Psychic complaints may occur in two types of individuals: (1) those who by reason of some congenital or protoplasmic fault are mental defectives, or (2) those who have normal mentality and from disease or other reasons become psychically deranged.

Mental Defects. In eliciting a complaint, it may soon become obvious that the patient has a mental defect.

The simple primary amentics comprise idiots, imbeciles and morons of various grades or degrees. In 1934 the American Association on Mental Deficiency (H. M. Pollock reporting) adopted the following criteria for grading mental defect: "An *idiot* is a mentally defective person usually having a mental age of less than 3 years, or if a child, an intelligence quotient less than 20 An *imbecile* is a mentally defective person usually having a mental age of 3 years to 7 years, inclusive A *moron* is a mentally defective person usually having a mental age of 8 to 12 years, or if a child, an I Q (intelligence quotient) of 20 to 49 inclusive.

"As a rule the upper limit for a diagnosis of mental deficiency should be an intelligence quotient of 69, but this limit should not be adhered to in cases where medical, social and other factors clearly indicate that the patient is mentally defective.

"For purposes of this classification in computing intelligence quotients of adults the mental age is to be divided by sixteen The intelligence quotients mentioned above are based on the use of the Stanford revision of the Binet-Simon test "

An *idiot* by definition has a mental age of less than 3 years Such a person, no matter what chronologic age he has attained, cannot be expected to guard himself against physical danger any more than a normal child of less than 3 years of age can do.

Idiots are rarely able to form articulate words In some idiots rhythmic movements, such as swaying or rocking of the body, are almost constantly sustained during waking hours About 50 per cent of cases of idiocy are due to developmental failure in the prenatal period and 30 per cent to birth injury. Idiots constitute about 5 per cent of all defectives

Some idiots are good-natured, others are ill-natured and irritable Idiots often show organic nerve lesions or anomalies in the shape of the skull. About one third of all idiots have epilepsy.

The only difficulty in diagnosis lies in delimiting idiocy from imbecility in cases on the borderline

In *mongoloid idiocy* the child has a peculiar physiognomy, which has led to the name mongoloid There is no agreement as to the etiology of mongoloid idiocy. There are those who believe that the condition is heritable, while others believe, as indicated in the empiric risk of the condition, that it is largely attributable to aging parents

In mongoloid idiocy the face is flat, the nose wide and flat, the malar bones are prominent, the eye-slits narrow and oblique, the eyelids reddened, and the cilia scanty. The cheeks are dull in color with malar prominences flushed. The skull is round, the occiput flattened. The tongue is enlarged and has huge papillae, the dorsum of the tongue is wrinkled and the tongue is often protruded The musculature

is relaxed and soft and the joints can be twisted in remarkable attitudes. The tends to be obese and is very susceptible to infections Many malformations thro out the body have been observed in cases of mongolism These children usuall of infections before they reach the age of 20 years

Imbeciles by definition vary more widely in mental capacity than idiots, for are from 3 to 7 years of mental age They learn to walk, talk, dress themselves follow simple instruction in order to perform simple tasks They can avoid ord physical danger inherent in a simple environment Imbecility originating from fective germ plasm often is accompanied with various physical anomalies and mas of degeneration. About 20 per cent of defectives are imbeciles

Morons by definition more nearly approach the lower limits of normal men than imbeciles They learn to read and write but few attain more than the f grade. If proper supervision is at hand they can do simple routine work The not capable of consistent planning or sustained effort under stress

No better etiologic factors can be assigned for simple primary amentias than alc ism, syphilis, tuberculosis, toxoplasmosis, advanced age of parents, metabolic de consanguinity, toxemias of pregnancy, birth injury, prematurity and morbid here It seems reasonable, however, that a defective germ plasm is the real cause of pri amentia in most instances As cited by Keith in his new *Theory of Evolution*, inbre increases the chances of a defective offspring Likewise inbreeding will make good plasm better

MENTAL DEFECTS ASSOCIATED WITH DEFORMITIES Of the defects of the brum that lead to imbecility may be mentioned hemorrhages, encephalitis, int hydrocephalus, meningitis and porencephaly In some families imbeciles ap singly through a series of generations, suggesting morbid heredity

Mental deficiency may be associated with *microcephaly* In these defective head is of less than the normal size. The condition seems to be due to a defe

[illegible] ... indicator o amount of intelligence which may reside in a very small brain. Most of these chil are delicate and succumb easily to infections.

Microcephaly is to be distinguished from the primary amentias and conge diplegias, in which the head is often somewhat less than the average size, but r so small as that of the true microcephaly

Macrocephaly is characterized by hypertrophy of the brain and by mental ciency It occasionally occurs in more than one member of the same family. Be congenital macrocephaly is so designated, hydrocephalus, brain tumor and c conditions which might cause increased intracranial pressure and enlargemen the head should be excluded. The clinical diagnosis cannot be established wit a complete study of the ventricular system

There is a type of amentia associated with the excretion of *phenylpyruvic in the urine*. The disease seems to be inherited as a recessive characteristic. mental defect is severe. There are muscular rigidity, alterations of posture and tremors and athetoid movements. The diagnosis is made on the basis of urin and the finding of phenylpyruvic acid

The most practical test for the detection of mental defects of these types sists in the lack of ability of the individual independently to meet the world a end of adolescence.

. The parents bring the mentally defective child to the physician and solicit his l in regard to the abnormal behavior they have observed in the child.

A systematic psychic examination of the cognitive, affective and conative funcıns (intellect, emotion, will) is necessary, in order that the mental equipment of e suspected defective may be compared with the average. The possibility of an isting myxedema, cretinism, mongolism or infantilism should always be kept in ind.

Temperament. The peculiar physical character and mental cast of an individual termed the temperament. The temperament of an individual becomes evident in l instances of interpretations of a complaint. Various classifications of temperaents have been offered. All of these have descriptive value but they fail to explain e temperamental differences observed Here two meanings of the term are emoyed: (1) The popular meaning of temperament is disposition The disposition of ı individual implies the natural temper or constitution of the mind, and characteres the individual as amiable or irritable. (2) The scientific classification of temperaents as formed by Kretschmer consists of the cyclothymic and schizothymic or :hizoid types.

CYCLOTHYMIC TEMPERAMENT. The cyclothymic temperament is characterized by ›o contrasting qualities of disposition: (1) cheerful and vivacious (hypomanic) and !) sober and serious (melancholic). The cyclothymes are predisposed to the developent of manic-depressive or affective psychoses. The cyclothymic temperament is often ıbdivided into hypomanic and melancholic types

Hypomanic Temperament. The hypomanic are free from internal inhibitions. They e usually energetic, given to fleeting enthusiasms and easily swayed by new impressions heir judgment is superficial and they have a ready excuse for their failures. They are lept at talking themselves out of difficulties

Melancholic Temperament. The melancholics tend to be easily depressed. They often ‹press regrets and feelings of inadequacy and hopelessness They are preoccupied with ork, feel responsibility, tend to suffer and cry in silence.

A tendency to hesitation, indecision and caution is characteristic of them.

SCHIZOTHYMIC TEMPERAMENT. The schizothymic temperament is characterized by ıcongruities of the feeling-life. In adolescence these individuals are usually willful, ısobedient, headstrong, moody, stubborn, ill-tempered, easily offended and resentful of dvice, supervision or correction The self-confidence which often characterizes these ıdividuals is of compensatory origin and arises from a sense of insecurity.

The sensitive schizoid is lonely, imperfectly understood and isolated The schizoid ; often ambitious, conscientious, meticulous and perfectionistic.

Schizoids may have an imaginative attitude toward life and its experiences, but may ıck the finer sensibilities. They may become cold, reserved individuals who are frequently :alous of those more happily adjusted

Personality Attitudes. Closely allied with the temperament of an individual ıre the personality attitudes which are known as extroversion and introversion, or imply the individual is designated as an extrovert or an introvert.

The direction of interests determines whether or not the individual is an extro/ert or an introvert. The extrovert possesses an abundance of energy which is di:ected to objects and affairs outside himself. He is energetic, aggressive, friendly, sociable and self-confident so long as these attitudes serve his needs The extrovert lacks the delicacy of feeling which is possessed by the introvert.

The introvert may possess the same amount of energy as the extrovert but it is directed toward himself, although not in the sense of selfish advantage at the expense of others The introvert often seems cold and aloof. The introvert tends to be serious and sensitive and frequently is lacking in self-confidence and boldness of activity. Some introverts masquerade under the guise of the extrovert. In such a conversion the introvert may overcompensate and become overbearing and domineering The definite types of personality attitudes predispose to certain mental illnesses, for in-

stance, the extrovert is predisposed to an affective or manic-depressive reaction; introvert may develop schizophrenia

The complaint which the patient makes to his physician may be revealing o defect in temperament

Psychopathic Personality. If an individual possesses mental inadequacies a deviations which are neither psychotic nor feeble minded, and if these aberrati render him unable to participate in satisfactory manner in social and cultural re tions with those about him, the condition is known as psychopathic personality.

Psychiatrists define various types of psychopathic personalities, for instance, stable, excitable, impulsive, egocentric, liars, swindlers, antisocial and quarrelso (Kraepelin) Here, however, mention will be made of pathologic liars and swindle antisocial personalities, sexual psychopaths and persons with situational psychos

Pathologic liars and *swindlers* are of agreeable manners and optimistic. Th select as their dupes the credulous with whom they make social or business conta They distort facts about themselves concerning their own attainments and kno edge in order to profit at the expense and humiliation of their victims The credul individuals, for example maids and matrons alike, often are blackmailed for sex fenses Money and sums from other sources may be obtained by the swindlers su posedly for investment purposes The pathologic liars and swindlers are unsta and are incapable of accepting responsibility or are unwilling to do so

The individual who has an *antisocial personality* is affectively cold and has acceptable, constructive expression of the striving functions He or she rarely fe remorse at offenses against person, property, society or law Many take pleasure a feel pride in their ability to offend moral, religious and legal standards

Sexual psychopathy is manifested in some by an abnormal sexual goal, as homosexuality, and in others by the gratification of the impulse by abnormal metho as in sadism, masochism and exhibitionism

Many of the so-called *situational psychoses* represent schizophrenic, affective paranoid reactions which occur under circumstances involving great emotional d tress, and they thus represent attempts to escape from the hard and uncompromisi reality of some specific, difficult situation Frequently situational psychoses are the nature of confused states or paranoid episodes, or of attacks of irritability, e citement or depression

Patients afflicted with the difficulties described may complain of them, or th may try to conceal their difficulties, and the complaint may be made by others. Lik wise in any of the psychoses the complaint may be expressed by the patient or ma by the family or friends of the patient

Complaints of the abnormalities just described are less likely to be made by t patients than by relatives, by those duped or by officers of the law

Character Disturbances and the Psychoses. The psychic functions in m have evolved from development of the simple instinctive tendencies In each instin tive tendency there are the constituents of knowing (cognitive), feeling (affectiv and striving (conative). Feeling and striving are considered as character, as co trasted with cognition and intellect The intellect seems to be an instrument whi has been evolved in order better to satisfy man's desires by activities through kno ing. In order that a human being may know how to adapt and respond to the eve changing forces of physical and social environment, there must be ever prese adequate cognitive, affective and conative functioning of the mind

Complaints of psychic origin often represent faulty technics of adjustment, ne rotic compromises with reality, and the results of various protective and safe devices employed by the patient in order to serve the ends and aims of the perso ality. In order to understand the complaints of a mental disorder, one must have a understanding of the forces that have gone into their formation, as a means to likely ascertaining what the patient is reacting to and expressing in his com

certain instances the services of the psychiatrist may be required for a full ›oration.

Knowing (Cognitive) Defects. Complaints originating as a result of disturbed ctions of cognition and intellect are referable to (1) the sense organs, (2) the rons of peripheral nerves which conduct impressions through the central nervous em to the higher centers of integration, and (3) the integration and combination hese new impressions with old ones to form perceptions and judgments that are agreement with objective reality How far a given human being, the patient, is lthy or ill and the reason therefore depend on the degree of disturbance of the chic and the somatic functions. It is desired to determine how far the patient is able or incapable of making adequate responses to the psychic and physical uencès of the environment in which he lives

THE SENSE ORGANS The nerve beginnings in the organs of sense, namely, the s, ears, nose, taste buds, touch spots in the skin, and the nerve beginnings in the scles, bones, joints and viscera are essential to the functions of knowing.

The various end-organs, or receptors, are so constructed as to analyze the en- onmental energy and select certain kinds which are transformed in the receptor l give rise to a nervous impulse On arrival in the appropriate preordained area the brain this impulse produces a visual, auditory or other sensory image, the erpretation and meaning of which will depend on the previous experiences of the erpreter The elements which are likely to lead to misinterpretations of these ages, with resulting illusions, are deeply intense affective states or strongly urgent ves and impulses. A misinterpretation of normal stimuli arriving at the higher nters of integration is an *illusion*. The nature of illusions is likely to be determined the prevailing trend of the patient's preoccupations. In confused, toxic states ual perceptions are more likely to be misinterpreted than perceptions involving ier senses because the sensory stimuli and impressions are not sharply defined; s the common occurrence of visual illusions in alcoholic and other intoxications

A more serious falsification of perceptions is the formation of image symbols en there is no discoverable impulse created by the stimulation of a receptor. A ntal image projected outward as a perception in the absence of an external stim- is is an *hallucination*. An hallucination lacks a basis of reality It is created by the tient's own mind, but it constitutes an actual part of the mental life of one thus ected.

The content of perceptions in hallucinations is so intimately subjective that the tient cannot ignore them They absorb the attention completely and reality is ide to harmonize with them The nature of the material hallucinated is influenced the psychologic experiences of the patient.

During the early and acute stages of a toxic psychosis hallucinations are more irked and may be of no great importance in these disorders The hallucination iich occurs with a clear mind is of serious diagnostic import. Hallucinations are equent when attention slackens and there is time for daydreaming

In hallucinations the images are cast in that sense best fitted to symbolize them allucinations of *hearing* are most frequent Feelings of guilt, for example, may best expressed in spoken language, and so the patient hears accusing voices. The ices arrange the words in sentences and give commands addressed personally to e patient The commands are often convincing and compelling and may therefore erce the patient to overt acts

In the deliria of acute infectious diseases or of toxic psychoses hallucinations of *ght* occur most frequently. The classic form of mental disease accompanied by sual images is delirium tremens The images are almost always of a terrifying iture

Olfactory hallucinations most commonly represent feelings of guilt and often cur in schizophrenic states.

Hallucinations of *taste* are uncommon and when present they often are associ- :d with hallucinations of smell

Tactile hallucinations are common in toxic alcoholism and cocaine addiction

Sexual hallucinations are almost always limited to schizophrenia. The hallucina- ons pertain to size, shape or the absence of the external genitalia

All of these abnormalities related to the sense organs are likely to be perceptible the patient's complaint, as he tries to express it to the physician

THOUGHT The joining of ideas and the formation of new ones constitute the unction known as thinking. Thought processes may be disturbed in production, rogression and content.

In mental health the stimuli for thought come from environmental reality and hus thought is rational or realistic. In mental disease the production of thought comes from the inner mental life and is not corrected by reality. For instance, schizo- phrenic thinking finds its origin in complexes, wishes, drives and other motivations not recognized by the patient and operates for the purpose of providing substitute forms of satisfaction Thought wanders without correction by realities

Disorders in Progression of Thought. The rate and manner of progression of thought, if revealed at all, are disclosed by the stream of talk. Of course it is expected that during normal small talk for the purpose of entertainment, there may be a lack of logical and coherent sequence of related ideas Beyond this small talk for entertainment purposes there may be disturbances of the stream of thought in which the thinking processes appear to run too quickly and in which at least some ideas are not completed This condition is known as *flight of ideas* In flight of ideas words of similar sound call up the new ideas This new association of ideas is known as *clang association* and may lead to a pun or a senseless rhyme

The opposite to a flight of ideas is *retardation* of the thought processes In retardation the initiation and movement of thought are slow. The patient's thoughts come slowly and are expressed by a slow speech and in a low tone. Retardation in minor degrees may be normal, when fully developed, however, it is observed chiefly in the depressive phases of the affective psychoses but also may be present in schizophrenia.

A disorganization of syntactic structure of thought with a lapse into disjointed phrases or even into parts of sentences is known as *incoherence* Incoherence occurs particularly in schizophrenia, a disease in which the thinking is characteristically dominated by complexes.

When both expression and progression of thought suddenly but temporarily cease, the process is known as thought obstruction, or *blocking* This often occurs in petit mal epilepsy.

When there is a tendency for the associative evolution of ideas which are determined more by affective factors than by logical reasoning, the strongest feeling tones dominate. An idea which comes to have an extreme feeling tone connected with it is spoken of as an *overdetermined* or *overvalued* idea An overvalued idea is an important determinant of behavior. Individuals possessing degrees of overdetermined ideas are frequently met, particularly in scientific circles and religious gatherings

A *delusion* is a false conception of a particular life situation. The trend of a delusion is determined by the prepsychotic personality problems of the patient The sources of these problems may often be found in thwarted trends and drives, frustrated hopes, feelings of inferiority, inadequacies, impelling desires, feelings of guilt and other affective preoccupations.

The psychologic purposes and needs for the satisfaction of which delusions are created fall into groups of well-defined mental mechanisms. For instance, delusions of grandeur arise from feelings of inadequacy, insecurity or inferiority, any conscious recognition of which is prevented by the exaggerated affective components of the

delusion. Delusions of self-accusation may arise from the repression of unacceptable trends and desires.

Unworthy desires, or troublesome and disowned aspects of the personality, when projected as hostility from the environment, are termed a *delusion of persecution*. Delusions of persecution permit a shifting of responsibility. Those in whom delusions of persecution develop have always been too critical, resentful, suspicious, unhappy, lonely, brooding and insecure, from a lack of friends with whom they could share confidences

When an individual interprets the remarks or actions of other persons, although in no way referring to the observer, as being significantly related to himself, and particularly if to him these remarks and actions express accusation or depreciation, the condition is termed *ideas of reference*. In paranoid states ideas of reference represent a projection of self-criticism onto the external world. In depressed states feelings of guilt often stimulate ideas of reference and may contribute to loosely organized paranoid delusions

When repression weakens, memories or ideas which would cause emotional pain, if admitted to consciousness, may give rise to depression. A *depressive delusion* is the rationalization of a sense of depression resulting from unconscious hostile tendencies felt toward innocent persons.

If an individual's attention is abnormally concentrated on his own body so that he is depressed and his thoughts are obsessively preoccupied with some bodily organ which is thought to be incurably diseased, the condition is known as *hypochondria*. Hypochondria often occurs in those who have shown a tendency to evade the responsibilities of life through illness Hypochondriasis occasionally is symbolic, as in schizophrenia, and as such it indicates a serious disorder.

An *obsession* is the result of thoughts which persistently thrust themselves into consciousness against the conscious desire of the patient. Obsessive thoughts may lead to compulsive acts In a compulsive act the patient feels impelled to perform it The act is often elaborate and repetitive so that it seems almost ritualistic.

Phobias are like the obsessive idea. The individual is filled with morbid anxiety and distress which constantly thrust upon him against his own will. Among the common phobias are fears of dirt, of bacteria, of cancer, of crowds or of closed spaces

Relationship to the Complaint If the physician has the confidence of his patient, the foregoing difficulties in relation to thought, if they have been experienced, are likely to be mentioned in the patient's complaint.

MEMORY. The memory may be phenomenally good, *hypermnesia*, or there may be a loss of memory, or *amnesia*, and in many instances there is falsification of memory, or *paramnesia*

Hypermnesia. Normally the impressions which arise from events which arouse the emotions are registered with more than the usual intensity, with the result that there is always a more vivid recollection of details of these events.

Amnesia In instances of physiologic disturbances of neurons from toxins, trauma or degenerative changes there may be organic amnesia Organic loss of memory is due mostly to an impairment of retention, though registration is somewhat affected. In the patient who has psychogenic amnesia the absence of memory is an active, defensive process The patient always is a hysteric who simply refuses to remember.

Paramnesia Paramnesia may be of different forms. 1 In *confabulation* the gaps in memory are packed full of fabrications which are without any basis of fact. Confabulation is observed in Korsakoff's syndrome but occasionally also in senile psychosis 2 *Falsifications* or *illusions* of memory are created in response to affective needs. They are frequently observed in the reporting of past events. In paranoid psychoses this tendency is highly developed 3. In the phenomenon of *jamais vu* there is a false feeling of unfamiliarity with situations that have actually been expe-

·ced These phenomena may occur in schizophrenia, psychoneuroses, epilepsy and in states of fatigue or intoxication

Dementia. Dementia is a permanent, irreversible loss of intellectual capacity. It occurs most frequently in cerebral atherosclerosis and neurosyphilis.

Disturbances of Consciousness Disturbances of consciousness are often associated with the acute stages of toxic, infectious or traumatic conditions and some ·l diseases A patient in a state of *confusion* is bewildered, perplexed and disoriented. The face presents a distressed and puzzled expression

In *psychogenic stupor* there is no suspension of consciousness, but the patient does not move The thoughts are dereistic. In toxic-organic stupor conscious thought processes are suspended

Delirium is usually associated with fever or toxic states. There is a clouding of consciousness, with bewilderment, restlessness, confusion and disorientation, and illusions and hallucinations may occur

Dream or twilight state is an affective disturbance of consciousness in which the patient does not recognize familiar surroundings In response to visual and auditory hallucinations the patient may run away from home or commit acts of violence. When ·l consciousness is regained, the patient may report that he felt as if he were ·ng and will have little or no recollection of events that occurred during the existence of the twilight state Such dream states occur for the most part in hysteria · in epilepsy They may end in delirium, as described, or they may pass into dissociated states, such as fugues and double personalities.

Disorders of Apperception Disorders of apperception occur in mental deficiency, in psychogenic diseases involving intense preoccupation, and in toxic and organic ·· In disturbances of apperception the patient has difficulty in understanding questions and unaccustomed situations and experiences.

Disorders of Orientation If a person does not know his position in reference to time, does not appreciate the situation both as to space and circumstances, and does not understand his relationship to other individuals, he is said to be disoriented. An individual may be disoriented in any one, two or all of these spheres, that is, the time, place or person Disorientation may occur in any mental disease in which there · extensive impairment of the memory

Relationship to the Complaint The patient may be sufficiently aware of these disorders of memory to complain of them, or they may have been noticed by others who will seek the physician in behalf of the patient

Functions of Affectivity or Feeling. THE PERVASIVENESS OF AFFECT The ·ctions of affectivity or feeling consist of the psychic phenomena known as feeling tones, moods and emotions Feeling tones accompany all sensations and ideas and ·e tinged by either pleasure or displeasure, both of which are conducive to states or emotions that may be termed moods Moods usually are prolonged states characterizing persons as having, for instance, a sunny disposition or a grouchy disposi· ·. Moods accompany all of the episodic emotional states of delight, disgust, joy, ·ief, love, hatred, anxiety, peace, anger and their modifications

Pleasurable Affects. Euphoria is a pleasurable affect The individual is imbued with a subjectively pleasant feeling of well-being Euphoria is most frequently observed in general paresis, multiple sclerosis and in some instances of frontal lobe ·mor Euphoria may readily shift to irritability. Euphoria is contrasted with an air ·f enjoyment and of self-confidence which radiates from some normal individuals.

A mood of entrancing, peaceful rapture and tranquil sense of power is termed ·*stasy.* A religious element is an essential part of the state because it permits of detachment from worldly things and the religious tenet of rebirth and thus purifica·n. Ecstasy represents the achievement of the maximum of wish fulfillment. The ·tion is observed in hysterics, epileptics and schizophrenics.

Depression. An affective dejection varying from mild downheartedness to stupor is known as depression. A reactive depression arises from sickness, bereavement, betrayal, loss of property, job or money, and from many other difficulties. Autonomous depressions arise from unrecognized affective factors the sources of which are beyond the patient's capacity for understanding.

Tension. Tension is characterized by a feeling of uneasiness, restlessness, dissatisfaction and expectancy. It is really a manifestation of anxiety.

Fright, Fear, Anxiety and Panic. Fear and fright are mechanisms intended for the preservation of life They are, therefore, comparable to pain. It is possible to abolish pain and fear temporarily and to a fairly predictable degree with certain drugs.

There are no essential distinguishing features between fear and anxiety. When the threat of danger is acute, fright seems to be the preferable term. When a continuous danger impends, it is proper to designate the reaction as one of anxiety.

Of fear in children and primitive man four aspects can be distinguished:

1 The *mimic* or *pilomotor reflex* is characterized by changes in the skin which, especially in animals, lead to a sort of masquerade. In man a lively reaction takes place in the skin under the influence of serious emotion. There may be shakes and vasomotor changes, and the face loses color. There is a feeling of intense cold. In some an unbearable itch and urticaria make an appearance. The skin may desquamate after a few days Spontaneous extravasations occur in face and legs, painful hypersensitivity of the skin, neuralgic pains, general hyperesthesia of the senses of perception, and complaints of cold and pain may be present, and chronic rheumatism may flare up

2 The *flight reflex* is expressed by mobilization of every facility to escape the danger There is an accelerated activity of the sympathetic system, with increased supply of epinephrine to the tissues, increased blood supply, halting of motility and secretion of the digestive organs or, in some cases, hyperfunction such as passage of bowel movements Reactions of the vascular system are prominent. Cardiac palpitations and sudden sthenocardiac pressure are well known. A weak heart may not survive The common distress reactions are gagging, anorexia, nausea and diarrhea Polyuria and involuntary urination are common A latent exophthalmic goiter may be made active Impotence, a feeling of paralyzed sexual functions, alternating drowsiness and sleeplessness often ensue.

3. A sudden stop to this aggressive activity is *panic.* There are a psychic stand against the threatened danger and a somatic mobilization All psychophysical possessions are geared for defense.

4. The popular expression "I was literally scared to death" may actually be termed the *death reflex,* as the clutching of objects in the hand at the time of drowning There is a general paralysis of functions, and cataleptic posture and a stiffening due to fear are present Cataleptic stiffening after great fright is often experienced In some cases disease symptoms which resemble parkinsonism, anxious eyes (proptosis), tremor of the hands, stiffening of muscles (a sort of decerebrating stiffness) ensue

The breathless stiffening of fright may cause in some an attack of asthma, a fear to breathe, not influenced by any therapy A chronic nervous asthma may result. There may ensue a drop in weight from loss of fluid due to profuse perspiration and internal secretory changes Paresthesia of the extremities, hands and feet going to sleep, and acrocyanosis may ensue.

Fear, whether of magic, evil spirits or the dark, is present in most men When resistance is lowered by disease, by shock or by psychic conflict, fear may become rampant Depending on early training of the individual, fear may develop of dark strange places, loud noises, high places, lightning, thunder, and the graveyard on a bright moonlight night

Inadequate Affect. This is emotional dulling characterized by a lack of sensitiveness to those experiences that normally give emotional response. The qualities of gratitude, sympathy, hope, anticipation, grief, regret, pride or shame are partially or completely lost.

Depersonalization. This is characterized by a feeling of unreality and of changed personality. It is a form of withdrawal from reality. The patient feels that he is no longer himself, but he does not feel that he has become someone else. There is a total loss of affective response, everything seems unreal. Depersonalization occurs in depressions, in anxiety, obsessional states, hysteria and in some schizophrenias. It is more frequent in intelligent, sensitive, affectionate, introverted and imaginative types of individuals than in other types.

Relationship to the Complaint. Evidence of abnormality of the affect (feeling tones, moods or emotions), if present, is very likely to appear in the patient's complaint

Conative or Striving Functions. The conative or striving functions of the human being relate to volition or will and action and timed behavior. The normal person strives to attain certain goals The basic or natural aims of this striving are self-preservation, race continuation, acquisition of knowledge and its dissemination, social intercourse and the appreciation of beauty, right conduct and all the will for the good things of life

Attitude is an acquired conscious desire or an unconscious predisposition to react in a characteristic manner toward a given type of person or situation

Disposition is a sum of the individual's tendencies as determined by the affective and conative components of his personality

Aggression is the deep-seated drive or pattern of the personality possessed by an individual who reacts in a positively forceful way Aggression carries the implication of will to power and, too, of hostility and attack. These tendencies may or may not be obviously expressed In the desirable individual the aggressive impulses are sublimated so as to serve to promote constructive forms of unselfish adaptation.

Ambivalence implies a combination of the use of the action sphere and the affective sphere of the personality. In manifest ambivalence the individual may be abnormally impelled by contrary drives

Disturbance of activity comprises states of (1) hyperactivity or overactivity, (2) decreased activity, (3) repetitious activities, (4) automatic obedience, (5) negation and (6) compulsion

In *hyperactivity* the patient is very busy but the activities often are not productive. The stream of talk expresses a flight of ideas. In *decreased activity* there is delay in starting an activity, and once begun, it is executed slowly *Repetitious activities* are variously expressed for instance, a constant repetition of an activity is *stereotypy*, a maintained immobility of position is *catalepsy* A cataleptic form of immobility is frequently observed in schizophrenics and it is termed *waxy flexibility* Schizophrenics perform many different sorts of mannerisms, such as grimaces, repeated gestures, and peculiarities of gait. Comparable repetitious activity in speech is observed A reiteration of speech is known as *verbigeration.*

Automatic obedience may be expressed by command automatism in which suggestions or requests are compulsively followed There may be a repeating of words or phrases which is termed *echolalia* When words, phrases or movements are initiated without command, these acts are termed *echopraxia.*

Negativism is a refusal on the part of the patient to do what is desired of him or is the performance of the opposite Extreme negativism is characterized by mutism, refusal of food, noncompliance with requests and resistiveness.

It may be a difficulty with the conative, or striving, function which causes the patient to seek the help of the physician If so, at least a hint of difficulty may be found in the complaint which the patient makes.

The Manic-Depressive Group of Psychoses. This is a group of psychoses characterized by manic states (manias), by depressive states (melancholias) or by mixed manic-depressive states. In some cases the patients suffer from only one attack, either of mania or of melancholia; not infrequently there is a regular recurrence (cycle) of the two opposite states of mania and melancholia, the single cycles repeating themselves, after shorter or longer free intervals, throughout the whole lifetime—cyclothymia.

THE MANIC PHASE. In the manic phase of this psychosis the patients experience and manifest an exalted mood; they tend to sudden changes in humor, to flight of ideas, to easy distraction of the attention In the exaltation everything is easy for the patient. The facial expression is happy, though subject to rapid change to anger. There are rapid changes in the direction of the ideas; the patient seems unable to hold an idea in mind, objects about him quickly altering the flow of ideas. There is a tendency to make rhymes, puns and alliterations. The pressure of activity exhibits itself as a preternatural loquacity, or in a tendency to excessive busyness, in the *writing of many letters, in the sending of many telegrams, in the making of unnecessary* purchases, in unnecessary traveling or visiting. Such patients are prone to indulge in sexual and alcoholic excesses

Mild forms of mania sometimes go unrecognized. The patients are often thought to be unusually healthy and vigorous. Once the patients are under observation, the superficiality of it all is easily recognized: the poverty of the underlying thought, the tendency of the mental associations to be influenced by sound, similarity and contiguity, the resemblance to mild alcoholic intoxication, and the absence of insight into the disease.

In the severer forms of mania there may be delusions of grandeur and of extravagant self-appreciation. The mood changes suddenly, without warning there may be an increase of irritability or an outbreak of anger and violence. The patient may attack the surroundings and explode into blackguardism. Patients of this type gesticulate, dance, yell, tear up their clothes or pull out their hair. In the severe forms of the disease they may eat, drink or smear themselves with urine or feces. Under all this maniacal excitement they experience no feeling of fatigue.

*In milder psychoses the orientation may be good, but in the severer forms, espe*cially those with many hallucinations, there are disorientation and confusion.

The patients lose weight rapidly from insomnia, lack of food and excessive movement After several months during which remissions and exacerbations occur, the patients may gradually improve, regain their weight, and return approximately to normal.

The manic states have a marked tendency to recur The first attack usually appears in youth

A maniacal attack of the manic-depressive group must be distinguished from (1) the maniacal attacks in dementia paralytica, (2) catatonic states of schizophrenia, and (3) hallucinatory confusion, or amentia

THE DEPRESSIVE PHASE The depressive phase or melancholic state of the manic-depressive psychosis is characterized by a pathologic sadness and a slowing of thought and emotion, associated with ideas of self-depreciation, ideas of poverty, ideas of sin and hypochondriacal ideas There is always danger of suicide. Digestion is disturbed and the bowels are constipated In the milder states the patients admit that they are sick, in the severe states they deny that they are sick, and may assert that they are just sinful

A large part of the involutional psychoses (senile, presenile, and climacteric psychoses) take the form of melancholia

The psychomotor retardation is the clue which distinguishes depressive phases of the manic-depressive psychosis from other forms of depression. The depressive phases of the manic-depressive psychosis must be differentiated from (1) depressive

phases of dementia paralytica, (2) depressive catatonic states and (3) depressive stages of senile dementia

Mixed Manic and Depressive States Not only are depressive symptoms prone to alternate with symptoms of exaltation, but states are met with in which some of the manic symptoms are combined with some of the depressive symptoms.

Relationship to the Complaint The patient's manner and speech when he makes his complaint often betoken one or the other of the states described, in great or slight degree.

The Paranoid States. By a paranoid state is meant a form of mental disturbance in which delusions, often systematized in character, and, especially, delusions of persecution and of grandeur, develop, with or without hallucinations.

A paranoid state may develop acutely, or it may develop and grow into a system, with progressive increase in delusions

The acute paranoid states are common in chronic alcoholism, taking especially the form of the acute jealousy-insanity. A similar jealousy-insanity sometimes develops in the puerperium or during lactation.

In the chronic paranoid states there are anomalies both of the intellect and of the emotions The disease develops so slowly that for many years a psychosis may not be suspected The patient is often hypochondriacal, retiring and suspicious, and suffers from ideas of reference Later, ideas of persecution appear, such as that people treat him badly, have it in for him, and are trying to poison him. Egocentric, grandiose ideas usually develop, such as ideas of unusual personality and powers, revelations from God, royal descent, ideas of reform and of discovery. In some cases hallucinations, voices and visions are prominent.

According to the nature of the delusions, the paranoid states are described as erotic mania, religious mania, political mania and jealousy mania. Paranoiacs are often homicidal

Most cases can be placed in one of two groups: (1) true chronic paranoia and (2) dementia paranoides In the latter the course is much quicker, the delusions are more nonsensical, and a high grade of confusion and dementia may soon appear

If the patient complains of being persecuted or if any of the other characteristics mentioned are evident in what the patient complains of, the physician should suspect the existence of a paranoid state—but he should not jump to the diagnosis

The Schizophrenic Psychoses (*Dementia Praecox*) The schizophrenic psychoses are often termed the psychoses of adolescence (dementia praecox), a group of mental anomalies presenting marked individual variations, but all having in common (1) development about the time of puberty or at any rate in the first half of life and (2) termination, sooner or later, in a dementing process of variable grade Not all reach a high grade of dementia, in some cases there is arrest with defect; in a very few cases there may be complete recovery. The cause is unknown.

In diagnosis the episodic states are less important than (1) the motor symptoms and (2) the development of a progressive dementia in youth.

Among the variable clinical divisions of these adolescent psychoses, three main types may be distinguished. (1) hebephrenia, (2) catatonia and (3) dementia paranoides

Hebephrenia. An enterprising youth, at puberty, or soon after, begins to stand still or to change his occupation frequently, has an exaggerated idea of his own importance, tends to occupy himself with the deepest problems of existence, shows pleasure in resounding phrases and dry proverbs, or abnormally devotes himself to puns and to practical jokes. Signs of feeble judgment soon appear. Victims of this disorder write long theoretical treatises, publish impossible books or undertake impractical careers Among the complicating episodic states may be mentioned sudden depression, excitation, anxiety or suicidal tendency. Each episodic state is followed by deterioration and by increase of apathy.

The disease usually goes unrecognized for some time, and is designated neurasthenia or hypochondriasis. Hebephrenia should be suspected in young persons with good memory and comprehension who exhibit loss of initiative, dulling of the higher feelings or a sense of failure of intelligence, particularly when no special cause for exhaustion is demonstrable and when the symptoms are not easily got rid of by general hygienic measures

CATATONIA. One of the commonest forms of insanity in young persons is that characterized by (1) specific catatonic phenomena such as negativism, command-automatism, stereotypy, grimacing, anomalies of speech and writing; (2) episodic states of stupor or excitation; and (3) a termination in dementia.

After a brief period of mental depression at the onset, the patients suddenly begin to behave in a surprising manner. Without apparent cause they may suddenly refuse to take food, or they may remain away from home without cause, or they may enter upon some "impossible" marriage engagement. Sooner or later, symptoms of catatonic excitation develop. In a few cases the patient attempts or commits suicide early in the disease, the family not having suspected the existence of a psychosis.

In catatonic stupor there is a peculiar alteration of psychomotor innervation, including negativism, in which the patient shows resistance (1) to any external influence on his will, and (2) to spontaneous motor impulses arising in himself, manifested by refusal to speak, to show the tongue, to take food, to swallow saliva. Muscles once innervated may retain their innervation, giving rise to the so-called stereotyped attitudes such as inclined head, crossed legs, snoutlike projection of mouth and turned-in thumbs. These attitudes may be maintained for hours, days or weeks, despite discomfort or ulceration from pressure.

In command-automatism, on the contrary, there is, in contrast with negativism, a preternatural suggestibility in the motor domain exhibited as waxy flexibility, echolalia and echopraxia.

In catatonic excitation violent, purposeless movements are made, often with loud cries and attacks on surrounding people; sometimes there are suicidal attempts. The so-called monotonous, or stereotyped, movements such as rhythmic swaying of body, rubbing of hands, movements of tongue, are kept up for hours or days at a time, and represent a transition stage between catatonic stupor and catatonic excitation

In intervals between excitation and stupor, certain peculiarities of behavior usually remain, such as grimacing, motiveless laughing or crying, coprophagy, peculiar writing, tendency to verbigeration, irrelevance and mannerisms. On the psychic side there are (1) a slow enfeeblement of the judgment, though the recording faculty and the memory may be good, (2) a dulling of feeling and apathy, (3) sometimes delusions, and (4) an incalculability and bizarreness of behavior.

Certain somatic signs may coexist· exaggerated reflexes; heightened mechanical excitability of muscles and nerves, increased secretion of sweat, sebum and saliva; amenorrhea, subnormal temperature, and remarkable variations in body weight. Remissions and exacerbations are common.

The catatonic phenomena, alone, do not suffice for the diagnosis of schizophrenia, for they are met with temporarily in other psychoses. The combination with mental enfeeblement is essential. The differentiation from dementia paralytica, epilepsy, hysterical twilight states or amentia is usually easy. In imbecility and idiocy the patients have been intellectually feeble from early childhood, whereas in dementia praecox there is a demonstrable deterioration of the mental powers The differentiation from a manic-depressive psychosis is not always easy, but the apathy, the negativism and the evidences of actual mental deterioration will usually be decisive.

phases of dementia paralytica, (2) depressive catatonic states and (3) depressive stages of senile dementia.

MIXED MANIC AND DEPRESSIVE STATES Not only are depressive symptoms prone to alternate with symptoms of exaltation, but states are met with in which some of the manic symptoms are combined with some of the depressive symptoms.

RELATIONSHIP TO THE COMPLAINT. The patient's manner and speech when he makes his complaint often betoken one or the other of the states described, in great or slight degree

The Paranoid States. By a paranoid state is meant a form of mental disturbance in which delusions, often systematized in character, and, especially, delusions of persecution and of grandeur, develop, with or without hallucinations.

A paranoid state may develop acutely, or it may develop and grow into a system, with progressive increase in delusions

The acute paranoid states are common in chronic alcoholism, taking especially the form of the acute jealousy-insanity. A similar jealousy-insanity sometimes develops in the puerperium or during lactation

In the chronic paranoid states there are anomalies both of the intellect and of the emotions. The disease develops so slowly that for many years a psychosis may not be suspected The patient is often hypochondriacal, retiring and suspicious, and suffers from ideas of reference Later, ideas of persecution appear, such as that people treat him badly, have it in for him, and are trying to poison him. Egocentric, grandiose ideas usually develop, such as ideas of unusual personality and powers, revelations from God, royal descent, ideas of reform and of discovery. In some cases hallucinations, voices and visions are prominent.

According to the nature of the delusions, the paranoid states are described as *erotic mania, religious mania, political mania and jealousy mania. Paranoiacs are* often homicidal

Most cases can be placed in one of two groups: (1) true chronic paranoia and (2) dementia paranoides In the latter the course is much quicker, the delusions are more nonsensical, and a high grade of confusion and dementia may soon appear.

If the patient complains of being persecuted or if any of the other characteristics mentioned are evident in what the patient complains of, the physician should suspect the existence of a paranoid state—but he should not jump to the diagnosis.

The Schizophrenic Psychoses (*Dementia Praecox*). The schizophrenic psychoses are often termed the psychoses of adolescence (dementia praecox), a group of mental anomalies presenting marked individual variations, but all having in common (1) development about the time of puberty or at any rate in the first half of life and (2) termination, sooner or later, in a dementing process of variable grade. Not all reach a high grade of dementia, in some cases there is arrest with defect; in a very few cases there may be complete recovery. The cause is unknown

In diagnosis the episodic states are less important than (1) the motor symptoms and (2) the development of a progressive dementia in youth.

Among the variable clinical divisions of these adolescent psychoses, three main types may be distinguished. (1) hebephrenia, (2) catatonia and (3) dementia paranoides.

HEBEPHRENIA. An enterprising youth,
still or to change his occupation frequen
importance, tends to occupy himself with
pleasure in resounding phrases and dry pr
puns and to practical jokes. Signs of feeble judgment soon appear. Victims of this disorder write long theoretical treatises, publish impossible books or undertake impractical careers Among the complicating episodic states may be mentioned sudden depression, excitation, anxiety or suicidal tendency. Each episodic state is followed by deterioration and by increase of apathy.

Acute Hallucinatory Confusion (Amentia, Acute Confusional Insanity, Acute Hallucinosis). In various infections, intoxications and states of exhaustion, especially after surgical operations, an abnormal mental state may appear, characterized by (1) the sudden onset of dreamy clouding of consciousness, (2) numerous, and very lively, disconnected hallucinations and delusions and (3) peculiar motor symptoms, consisting either of increased impulse to movement or of stuporous inhibition. The patients are confused, disoriented and incoherent; the recording faculty is markedly disturbed; the mood is anxious and variable. Some of the psychoses of pregnancy and of the puerperal period belong here. The patients usually emaciate rapidly, and they suffer from anemia, anorexia and insomnia

Amentia usually lasts from 6 to 9 months, or even longer than a year. Many die from inanition or from complicating infections; some commit suicide; about one third recover; a few go over into chronic mental disease.

Acute hallucinatory confusion is to be distinguished from (1) manic-depressive states, (2) epileptic insanity, (3) catatonic form of dementia praecox and (4) *dementia paralytica*.

Relationship to the Complaint. These manifestations are likely to be unrelated to the complaint which the patient originally made but may be related to those of a relative or guardian of the patient when the physician is called to meet a frightening emergency.

Psychoneurosis. Without a clear conception of the meaning of the complaint a practitioner of any form of the healing arts cannot fulfill the first obligation to the patient. This obligation is a correct diagnosis. In order to evaluate and assign a specific connotation to many a complaint or complaints a wide familiarity with organic and psychogenic illness is required. For it must not be forgotten that a psychoneurotic illness renders no immunity to organic illness, and likewise an organically ill patient may have and may have always had a psychoneurosis. The psychoneurosis may cause a very great difficulty in the interpretation of the complaint, for the somatic and the psychologic components in any given complaint must be disentangled. Until the somatic and the psychologic components have been separated it may not be possible to determine whether an illness is primarily or wholly psychogenic or whether it is somatic with coexisting psychogenic factors.

Emotional factors play a predominant role in the production of a psychoneurosis. These factors usually have begun to operate in early life and often are manifested by such disturbances as sleep walking, crying out in sleep, enuresis, disturbances of speech, food idiosyncrasies, delirium accompanying slight rises in temperature, destructiveness, emotional excitability, tantrums, phobias, compulsions, shyness, nail biting and other behavior affections.

In the psychoneuroses the personality remains socially organized. It does not deny the existence of reality, it attempts to ignore it. The interpretations of the environment remain unchanged, although certain elements are given abnormal affective values Repression is maintained, but the repressed material returns in a distorted form so that it is acceptable only to the patient.

It seems that many persons are unusually sensitive to the tension and conflicts of life and react to these with faulty reactions which impair the efficiency of the individual. These faulty reactions often create anxiety, which is one of the commonest and most important sources of psychoneurotic disorders. Anxiety disturbs physiologic functions In acute forms anxiety may produce spasm of the cardiac and pyloric portions of the stomach, intestinal spasms, hyperchlorhydria, diarrhea or constipation, palpitation, tachycardia, extrasystoles, vasomotor flushing and increase in body temperature (99 to 100 F) and respiratory distress The hands and face perspire The patient may have fidgety movements of hands or feet, the voice may be uneven or strained and the pupils may be widely dilated. Anxiety, therefore,

DEMENTIA PARANOIDES Dementia paranoides is an adolescent psychosis w is observed less commonly than either hebephrenia or catatonia. It is characte by a rapidly advancing delusional state in which the delusions quickly become surprising and nonsensical, terminating ... feeble-minded ... and are ... depression and excitation

At ... depressive symptoms usually predominate (insomnia, self-accu tion, "blueness," unrest, suspicion, sense of change in the environment) and id of reference prevail Illusions, hallucinations and delusions soon appear, the l consisting chiefly of grandiose, or of ... rapidly the ... The g ... characteristic, suggesting that of demen paral ... delusional falsifications of memory are common; the patient tells stor of marvellous experiences or of wonderful personal acts

There is no disease-insight. The apathy and indifference are characteristic. T dementia progresses rapidly with the appearance of incoherence in speech a writing

The diagnosis may be difficult at first, but is easy later on The condition mu be differentiated from (1) chronic hallucinatory paranoia and (2) dementia par lytica The age, somatic signs, and findings in the cerebrospinal fluid will elimina syphilis of the nervous system

The Infectious, Toxic and Exhaustion Psychoses. Under this heading are listed the initial deliria, febrile deliria and convalescent deliria of the infections and intoxications. In infectious diseases, delirium may appear at the beginning or during the main course, or in convalescence. These forms of delirium may occur in the course of any infectious disease There need be no relation between the height of the fever and the intensity of the psychic symptoms

FEBRILE DELIRIA In the febrile deliria the principal symptoms are (1) clouding of consciousness, (2) disorientation, (3) hallucinations, in addition, there may be (4) violent motor excitement, sometimes resembling that of mania, or (5) stuporous states

DELIRIA OF CONVALESCENCE The deliria of convalescence may appear suddenly, after the temperature has become normal They consist of (1) dreamlike confusion, (2) hallucinations and illusions, (3) occasionally delusions and (4) lively motor excitement The patients are usually anxious, and suffer from self-accusation, ideas of sin and other micromanic delusions, sometimes, instead, the state may be euphoric Stupor and excitation may alternate The outcome of these deliria is usually favorable

COMA, SEMICOMA, STUPOR AND CONFUSION *Coma* is a state of complete unresponsiveness to the environment The patient's reactions are limited to elemental reflexes, and even some of these are impaired *Semicoma* is a condition in which there is responsiveness to some of the elemental mental functions ... y name, reacting to noise and reacting to a ... t in the elemental reflexes ... in which ... execute f ... tongue *Confusion* is a s ... disturbance in the state of consciousness. The st ... elemental mental functions and reactions to simple commands are usually intact These patients present chiefly orientation difficulties.

in lies. They do not intentionally lie; this lying is but the pathologic phenomenon due to faulty reproduction. This faulty reproduction or transformation of memories is the so-called pseudologia fantastica or mythomania. These patients may have a complete but transient amnesia, or the amnesia may concern only persons or events

The feelings of the hysterical individuals are easily hurt. These individuals believe that they are misunderstood; they think that others do not pay them the attention that is their due or that others intentionally slight them.

Many hysterical patients may be unable to eat, or they vomit almost constantly, a condition termed anorexia nervosa. In others the abdomen may be continuously distended with gas, and this is termed hysterical meteorism, or the patient is called a bloater. In a few patients there may be a retention of the urine. A rare form of the disease is pseudocyesis; the patient, even without exposure, may think herself pregnant.

There may be transitory disturbances of consciousness such as hysterical twilight states, somnambulisms or trances The hysterical twilight states appear suddenly. There is confusion and silly childish behavior resembling simulation, and the condition may last for hours, days or weeks.

The hysterical trances, or lethargic states, may be characterized by sleep for days, weeks or months, though enough consciousness may be maintained to enable eating, drinking, voiding and defecating If aphasia is present, the patient may not have any difficulty in communicating in whispers The hysterical mute can communicate freely and correctly by writing.

Standing and walking may be difficult or impossible for the hysterical patient When the patient lies down, no disturbance of motility, sensibility or co-ordination can be made out. Some patients who cannot stand or walk can crawl or can swim. The condition is commoner in women than in men, and in young people than in old. It was formerly termed astasia-abasia There may arise a complete immobility on account of pain, although no cause for the pain is discoverable. The symptom is an hallucination in the pain sense Some of these patients during the attacks of pain manifest tachypnea and tachycardia.

The Ganser syndrome is a paralogia. It has been frequently present among prisoners of war awaiting trial As in many other hysterical states the hysterical protection from a full realization of the true situation affords a relative freedom from the anxiety which might otherwise be intolerable.

The recognition of hysteria is usually easy through the characteristic stigmas and through the exaggerated, often theatrical, character of the mental symptoms and the capricious, oscillatory course A hysterical patient also can have an organic disease.

Accident Neurosis (*Hysteria*) In persons of a paranoid tendency, those who are insecure, those who crave sympathy and attention, and those continuing work beyond mental or physical capacity, unpaid financial obligations or the failure to derive satisfaction from work all may predispose to a traumatic neurosis. The conviction on the part of the patient that there is the right to expect compensation may be a motivating factor. A period of time between the injury and the appearance of the mentally determined symptoms which is occupied with vague affective disorders often supervenes.

The symptoms of the accident neuroses, except in the matter of compensation, differ in no essential feature from those of other neuroses In those cases in which compensation is a participating motive, the patient remains unaware of such an influence and denies the desire for compensation Underlying feelings of guilt may be overcompensated and experienced as self-pity.

Occupation Neurosis. In occupation neuroses the patient, on attempting to execute some specialized movement performed in an occupation requiring the co-ordination of groups of muscles, suffers from a spasm of the muscles involved in

together with the various mechanisms developed to avoid it, constitutes an important factor in the development of psychoneurosis.

The psychoneuroses are said to be more frequent in women than in men. This is probably a matter of degree and sex of the author rather than of incidence. Therefore it is not well in diagnosis to infer that the numbers of psychoneurotic women greatly exceed those of psychoneurotic men, for they do not, and there is no reason that such should be true

Most neuroses of adults develop between late adolescence and 35 years of age. This is the period when the individual becomes confronted with the problems of adult adjustments and responsibilities It is the period when satisfying social, economic and sexual situations should be established. Frustrations in these fields may lead to conflict, anxiety and tension that are met only by neurotic mechanisms.

Hysteria. Hysteria is characterized by an abnormal mental state in which there is a disproportion between affective reactions and the stimuli that give rise to them. The suggestibility of the patient is heightened; the sudden transformations of the emotional states and the moods are best described by a marked degree of caprice

The disease is much commoner in women than in men It begins in adolescence, sometimes in childhood Most patients have a distinct infantilism in the psychopathic field Provocative causes are fright, anxiety and trauma.

Hysteria may begin with a feeling of constriction in the neck, or as a lump in the throat which cannot be swallowed, usually associated with loss of the pharyngeal reflex, and clavus hystericus, or pain in the region of the large fontanel, described as resembling a nail being driven into the head. Hysterical paralyses include hemiplegia, monoplegia, aphonia, astasia-abasia, ptosis and retention of urine Hysterical blindness and agnosia may be present in some instances.

Hysterical hyperesthesias include the so-called spinal irritation, or tenderness, on tapping the spinal column, ovarian tenderness on pressure in the region of the ovary, and various hyperesthetic zones occurring in any part of the body. Vasomotor and secretory lability is often expressed in hot and cold flushes and localized disturbances of sweating.

Hysterical convulsive seizures occur in which patients, without injuring themselves, sink down and assume, and maintain for some time, remarkable attitudes, such as the arc of a circle, or various pathetic or theatrical positions, or exhibit wild, rotating movements The attack can be terminated by a dash of cold water. The more common hysterical seizures include silly laughing, crying, coughing, hiccough, torticollis and muscular cramps.

Hysterical anesthesia may affect one extremity, one half of the body, or two extremities simultaneously, becoming ever more marked the more attention it receives. Often the anesthesia has a topographic distribution corresponding to areas of skin covered by certain articles of clothing such as the gloves, chemise, drawers or stockings. Exaggerated reflexes with false ankle clonus may be present.

The principal mental stigmas are a pathologic lability of mood, fallacies of memory, ideas of reference and lack of consideration for others

The hysterical patient is abnormally irritable; slight annoyance may lead to explosive behavior, and thus the expression, "he became hysterical" It sometimes seems as though the smallest stimulus excites the greatest reaction. The smallest and seemingly most insignificant incidents may give rise to convulsions and twilight states However, in an emergency the hysteriac may exercise a great calmness of action. The hysterical [illegible]
and the next moment, [illegible]
suspicious and sullen. [illegible]
periods, at the menopause and during pregnancy than at other times.

Hysterical patients are incapable of objective report. Often they seem unable to distinguish what they remember from what they imagine. They are thus often caught

Since the patient is perfectly sane, his complaint often is thoroughly descriptive.

Neurasthenia. Psychiatrists believe that the cause of neurasthenia is mental, and they no longer believe that a generally impaired or exhausted physical state in which the nervous system is drained of its energy is ever the cause of this disorder. In general diagnosis and the general practice of medicine a greater number of patients will be found who are physically exhausted and who do recover from the so-called neurasthenia after rest and success, than the number whose symptoms are due to a purely mental disorder such as repressed hostility, constant failure, frustration, disappointment, boredom and monotony

In neurasthenia there are a sense of mental and physical fatigability, tension, irritability, painful and other abnormal sensations and depressive affective tendencies. There may be complaints of dizziness, of a feeling of pressure on the head and perhaps of pain in the back of the neck. Often there is an intolerance of noise, bright lights and cold Gastrointestinal complaints such as gas, indigestion, constipation and diarrhea are common. Often the skin is flushed and sweating. In men an impaired potency and failures at intercourse may occur. Advancing age, not neurasthenia, is the usual cause of failures at intercourse in men who are more than 50 years old.

In the morning the patient awakes with a feeling of exhaustion, but as the day progresses there is improvement and by evening there is comparative freedom from the exhaustion. Many patients are shy and awkward and lack confidence in themselves They may be critical, dissatisfied, envious and resentful and may appear to take pleasure in finding fault with and annoying others

Psychoneuroses usually if not always show mixed features. It is most important to distinguish neurasthenia from the depressive form of manic-depressive psychosis and early schizophrenia These differentiations are made, by the psychiatrist, through time and observation

Relationships to the Complaint. The complaint voiced by the patient often is of diagnostic importance.

Hypochondriasis. Hypochondriasis represents a faulty type of adaptation to personality inadequacies with which a sense of disappointment or of guilt is associated T[illegible]
or bodil[illegible]
persons [illegible]
proportions The patient complains of these things.

Pain. Pain is of primary concern in most complaints The evaluation of pain in the complaint aids in diagnosis and management of the patient Pain is a sensation like smell, taste or vision It can be further compared to these sensations, for it is first a sensory perception This sensory perception is the pain threshold Pain has a reaction which is usually unpleasant but not always so. However, the important conception of diagnostic value of pain is the fact that sweating, tachycardia, digestive disturbances, anxiety, fear, terror, panic and prostration may be solely reactions to pain

Pain is a centrally integrated experience, the painful sensations being derived from impulses traversing specific pathways. According to Wolff and Hardy all fibers carrying impulses experienced as pain enter the spinal cord through the dorsal root ganglions After entering the cord these impulses are conveyed across to the opposite side, where the pathways are localized in the anterolateral portion of the spinal cord The fibers of the spinothalamic tract pass into the nucleus centralis posterior of the thalamus The cortical projection from the nucleus centralis posterior is predominantly to the postcentral convolution. It is probable, according to Wolff and Hardy, that the brain structures involved in pain perception occur in both hemispheres in the region of the central fissure.

The dual aspect of pain, that is, the distinction between perception and reaction

this act. The function of the muscles remains unimpaired when the same muscles are employed for the performance of some other act.

RELATIONSHIP TO THE COMPLAINT. In the complaint which the patient makes, he often reveals to the physician the hysterical nature of his underlying condition.

Psychasthenia (*Compulsion Neuroses*). Psychasthenia includes phobias, obsessive thinking and compulsive acts.

A *phobia* is a fear or dread associated with an idea, object or situation. Among the common phobias are fear of dirt, of bacteria or of certain animals. To many of these ideas, objects or situations Greek prefixes are applied, and thus are produced such terms as claustrophobia, the fear of confined spaces The phobic patient cannot avoid these fears, and if forced into an anxiety-producing situation, a state of agitation follows, the patient cries and shakes all over, may have general tremors and be unable to continue the duty at hand, and may become overwhelmed with panic

A phobia is often a fear of disease. Reassurances that somatic disease is not present often accomplish much in some patients. In others such assurance is of no value

Obsessive thinking is defensive in purpose. Distressing thoughts are composed of contents repugnant to the individual's conscious moral and esthetic feelings In a mild degree these are normal, for everyone has such thoughts, for instance, of tipping over a glass of water on the dinner table when too much formality is being practiced about the table

Obsessive thinking, characterized by persistent doubting, vacillation and indecision, may assume the form of *folie du doute*.

Compulsive acts are characterized by an irresistible urge to perform a certain repetitive, stereotyped act One of the commonest compulsive acts is that of getting out of bed after retiring, to check the gas or electricity or to see if the doors are locked The compulsive act reduces the intensity of anxiety.

Since everyone has defensive character traits, the diagnostic decision must often be arbitrary In the fully developed cases with the well-marked obsessive thinking, fears or compulsive acts, there is of course no question

A failure on the part of the patient to regard his phobias and compulsions as absurd indicates a schizophrenic origin

The depressions of manic-depressive psychosis may be accompanied by obsessive ideas

Anxiety has been defined as a state of heightened tension often accompanied by somatic reactions, usually in the vasomotor sphere It may arise when there is a threat to the personality. Anxiety often arises in association with frustrations related to property, job, money, sex or marital adjustment. The patient usually recognizes the tension and anxiety-producing agent, and often there is nothing that can be done about it.

The anxiety is often expressed by symptoms of depression, irritability, restlessness, psychosomatic disturbances, outbursts of aggressiveness, attacks of weeping and feelings of inadequacy and inferiority accompanied, perhaps, by a paranoid attitude. There may be difficulty in falling asleep, disturbance by fearful dreams, suffering from coarse tremors or trembling. The hands and feet are cold and clammy. The patients are absent-minded. There may be periodic acute, panic-like exacerbations lasting an hour or two These acute attacks take many different forms of representation, such as rapid heart action, precordial discomfort, nausea, diarrhea, desire to urinate, dyspnea and a feeling of choking or suffocation. The pupils are dilated, the face is flushed, the skin perspires, the patient suffers from paresthesias and tremulousness, feels dizzy or faint, and often has a sense of weakness and of impending death. The patient may express beseeching and apprehensive appeals for help.

sensory peripheral nerve fiber or a nerve trunk be injured, the threshold for pain is altered or obliterated. In the central nervous system, the pain threshold is altered or obliterated by spinal cord injuries. Lesions in or near the internal capsule of the brain may elevate the pain threshold.

The most important alterations of the pain threshold to be evaluated in the complaint are those resulting from psychologic factors These factors may raise the pain threshold; for instance during intense emotion, as during fright, severe injuries may be sustained without knowledge. Autosuggestion, hypnosis, distractions, malingering and mental concentrations all raise the pain threshold Anxiety, tension and fear seem to lower the pain threshold A lowered pain threshold is never solely due to structural disorder of the nervous system.

THE LEVELS OF PAIN INTEGRATION IN THE CENTRAL NERVOUS SYSTEM. There are three levels in the central nervous system at which pain may be integrated: the tectum mesencephali, the thalamus and the cerebral cortex.

In the tectum mesencephali the appreciation of pain is no more than a feeling tone and therefore probably is closely related anatomically and physiologically with the activity of the hypothalamus, its powers to perceive pain having been taken over during the process of evolution by the thalamus.

The fact that pain is relatively little influenced by small cortical lesions is the result of the numerous pathways which are provided by the thalamus for the passage of pain sensation to the cortex

The appreciation of pain stimuli at the cortical level is modified by the state of activity of other cortical centers so that the perception may be aggravated in some instances and prohibited in others.

Wolf has named six basic mechanisms which are responsible for headaches of *intracranial* origin These are (1) traction on, and displacement of, the great venous sinuses or traction on the veins that pass to the venous sinuses from the surface of the brain; (2) traction on the middle meningeal arteries, (3) traction on the large arteries at the base of the brain; (4) distention and dilatation of intracranial arteries; (5) inflammation in or about any pain-sensitive structure of the head; and (6) direct pressure by tumors on the cranial nerves containing pain-afferent fibers

The *headache associated with the fever* of acute infections is due primarily to the distention of the intracranial arteries The spontaneous increase and decrease of intensity of the headache of fever parallel the changes in amplitude of pulsations in these arteries The amplitude of pulsation of the cerebrospinal fluid in the headache of fever is greatly increased during the fever. These amplitudes of pulsation of the cerebrospinal fluid during fever headache are in marked contrast to the amplitude of pulsation in migraine, which is not accompanied by such a disturbance It may be that these pulsations account for throbbing headaches of fever

Headache from intracranial hypertension or disease is usually referred pain from the affected intracranial pressure Pain referred to the head from disease of tissue not in the head does not occur. Fever is often accompanied by headache, but this is not referred pain

Headache is a common early symptom of a space-occupying lesion within the skull, sometimes it is the initial symptom The absence of a headache, however, does not preclude the possibility of a space-occupying intracranial lesion. The symptom, headache, as arising from intracranial pressure, always requires assessment.

The headache from a space-occupying lesion, intracranial hypertension, renders the sufferer clearly intensely preoccupied with pain, and the questions and physical examination are but an addition to the burden of the pain These patients observe an economy of movement and of speech, since effort aggravates the pain. The pain is never spoken of as continuous over long periods, since organically determined headache is never so continuous, but always is subject to intermission over varying

to pain, is apparent and is easily appreciated in the case of heat, light, touch, cold and olfactory perception. The reaction pattern of the organism to noxious stimuli has many co[illegible]ponents Reaction to pain is modified by conditioning experiences, such as [illegible]tement of a game or combat, the apathy that accompanies tissue damage [illegible] certain religious and mystic practices, and the indifference to tissue damage during sexual excitement.

Total absence of the usual physiologic behavioral responses to noxious stimuli is rare Ford and Wilkins described three children with lack of reaction to pain rather than absence of pain as sensation They could appreciate light touch and could distinguish between warm and cool test tubes and between the head and the point of a pin. They were, however, indifferent to damaging stimuli Kunkle and Chapman described a young man who had almost complete insensitivity to pain and attacks of unconsciousness beginning in childhood Boyd and Nie described an otherwise apparently normal girl, 7 years old, who was completely insensitive to pain The usual painful responses could not be obtained by any stimulation She was able to distinguish sharpness from dullness, and the senses of touch, vibration, position and agnosis were normal. Boyd and Nie suggested two hypotheses to explain the patient's indifference to pain (1) There exists a congenital structural defect with incomplete neural connections and communicating fibers in the postcentral area with consequent inability to organize the complex concept of pain (2) There is no neurologic defect, but there is indifference to pain, which represents an aphasia-like disturbance

McMurray reported an exhaustive study of a patient with universal insensitivity to pain At no time, during any of the experiments in which noxious stimuli were used, did the patient report a sensation or feeling that could be interpreted as a report of pain Consistent with this was the complete absence of any observable signs of painful experience

Varieties of Pain. Two varieties of pain are recognized, superficial and deep Superficial pain is characterized by the quality of localization and has the components of sensations described as pricking, sharp, burning or itching, it incites the action of fight or flight Deep pain possesses the qualities of a diffuse aching or of a colic It incites the actions of withdrawal, forces a cessation of activity, and causes the affected one to seek protection Deep, severe pain may cause nausea and vomiting

Threshold of Pain. *Pain perception* is the threshold of the amount of stimulus required first to produce a painful sensation. In superficial pain the pain threshold can be elicited by heat, pinprick or chemical agents The threshold for deep pain can be elicited by electric or mechanical means such as a faradic current or the stretching of a hollow viscus The determination of pain threshold experimentally as well as in practice is based solely on the accuracy of the verbal report Despite the inaccuracies of the verbal report, the pain threshold in man is relatively stable and uniform The threshold for the perception of pain is found to be of the same order of uniformity as is the pulse rate, the number of leukocytes of the blood, or the blood pressure. The difference of pain threshold in different individuals lies in the individual reactions to pain. Generally it may be asserted that the alarming experiences aroused in the mind of the patient are the most distressing aspects of pain. For instance, morphine does not discontinue the perception of pain but it does remove the fight-flight-anxiety reaction of the sufferer

The pain threshold, like the other somatic components, may be altered. The pain threshold is lowered by traumatic deformation, denudement, or injury of tissues near the sensory nerve endings responsible for the reception of pain stimuli For instance, a mildly sunburned or a frost-bitten skin is twice as sensitive as a normal skin. The threshold for pain is raised or obliterated by local anesthetization. If a

then is carried, in this neuronic pathway, to the brain, and is perceived as coming from the distribution area of the second neuron.

The most numerous and important of reflected pains are those due to pathologic changes in the internal viscera The viscera of themselves have no sensation of pain, as elicited by ordinary pain-producing stimuli, but when the viscera are irritated, the stimuli are carried to the cord and react on the cord cells, and impulses are produced and sent out as motor impulses or are carried to the brain by the neurons of these cells where they are produced as pain At the same time, the adjacent set of cells become irritable and react abnormally to all stimuli reaching them from the periphery. In this phenomenon lies the origin of the hyperalgesic zones of Head which are responsible for several peculiarities of pain production.

Transferred pain may have varying degrees of two components: (1) The stimulus passes from the neuron in which it is originally present, over an intermediate neuron, to a third neuron, in the area of distribution of which it is perceived as being present (2) In other cases the sensorium mistakes the peripheral distribution of the pain, as in degeneration of the posterior roots (tabes), or of the ganglia and posterior columns or cornu of the cord.

Examples of pain transferred to a homologous segment in the same relative position on the opposite side of the abdomen are found in appendical and ovarian diseases, pneumonia and pleurisy. Examples of higher and lower reference are found in those cases in which the pain of pneumonia is transferred to the appendical region, or in which the appendix causes pain which is transferred to the thorax.

The term crises has been applied, under certain conditions, to paroxysmal attacks of pain of great severity It is accepted that a pain crisis consists of a paroxysm of pain as violent as human nature can endure, accompanied by excessive functional activity of the part attacked, but disappearing as rapidly as it appeared, and that it is associated with a condition of undisturbed functional activity of the affected viscera between the paroxysms.

Tissue susceptibility to pain is determined by the blood supply of the organs. The organs which are the richest in blood supply generally suffer the greatest pain and, with the exception of the bones, the organs poor in blood supply have little, if any, pain

Clinical Evaluations of the Complaint of Pain. Often much time is wasted if too long is spent on inquiries into details of location, situation and distribution of pain, the degree of itching and the occurrence of dizziness as complained of by the patient

Effeminate men and wordy women are inclined to exaggerate in recounting their symptoms A statement made with a cheerful countenance that the speaker is at the moment suffering horrible agony does not square with the facts; the combination of cheerful manner and exaggerated speech is of diagnostic value as indicative of self-deception, hysteria or a habit of chronic overemphasis.

In the majority of cases in which really severe pain is present, certain symptoms are manifest that cannot be simulated. The respiration is increased in rate, the pupils are dilated, the skin is wet with perspiration, the pulse is likely to be tense, there is a feeling of faintness, and frequently a large amount of urine is passed within a brief period after onset.

In the patients' manner of describing pain there are differences that already have been implied Some patients, as a matter of pride, practice understatement of their subjective sensations, whereas others from various motives habitually magnify their suffering and, in most instances, without the slightest intention of deception This mental attitude arises largely from a desire to obtain relief by impressing the physician with its urgent necessity

Variations in descriptions and perhaps in pain sensibility are racial as well as individual Persons of Semitic stock and members of Celtic and Italic groups appear

periods of time if it is of long total duration. Freedom from pain is admitted without emotional difficulty by the patient, and in the periods free from pain an attempt is made to return to accustomed activity (Walshe).

Histamine headaches are primarily due to dilatation and stretching of the pial and dural arteries and their surrounding tissues. The large cerebral arteries at the base of the brain, which include the internal carotid, the vertebral and the basilar arteries and the proximal segments of their main branches, are chiefly responsible. The fifth cranial nerves are the principal afferent pathways for the pain felt in the frontotemporal and parietal regions of the head. The ninth and tenth cranial and the upper three cervical nerves are the afferent pathways for the pain felt in the occipital region of the head.

In *migraine headache,* aberrations in the tension of the extracranial and possibly the dural branches of external carotid arteries may be responsible for the cephalalgia It seems likely that the point of origin of the scotomas of migraine is situated in the cranial cavity.

A *psychogenic headache* is commonly described as continuous and unremitting over long periods of weeks, months or even years. It responds to none of the usual analgesic drugs. This headache is described by the psychoneurotic as terrible, agonizing, as if corkscrews, knives or needles were piercing the head. When questions as to locality and quality of the pain are pressed, the patient's answers become vague, and "pains" are sensations of weight, pressure, or constriction and not real pain at all In the hysteric these accounts are commonly given with animation and evident satisfaction, while the anxiety neurotic is plunged in gloom and self-pity In these patients there is no true pain, but an image of pain conjured up by the patient and subjected to those processes of progressive elaboration to which mental images are prone

It has generally been believed that the majority of headaches *following spinal anesthesia* are the result of leakage of spinal fluid through the dural puncture, with subsequent changes in cerebrospinal fluid dynamics, loss of cushioning effect on the brain and resulting pain owing to pressure or traction, or both, on sensitive brain structures and large vessels

The mechanism responsible for the production of headache after *lumbar puncture* is not clear. At present there is no better theory than that accounting for the headache on the basis of a lowering of spinal fluid pressure by the removal of spinal fluid and loss of more fluid by leakage after the needle is withdrawn

Aberrations in the Central Projection of Pain. *Propagated pains,* which are felt in areas other than those in which they are produced, are classified as associated, referred, projected, reflex and transferred pains. This classification is important to remember when the complaint is evaluated.

Associated pain depends for its production on transference of stimuli from one nerve cell to another. In some cases the means by which the stimuli are transferred cannot be determined.

Referred pain is that class of pain in which the irritation occurs along the course of the nerve fibers, and the pain is felt as being produced in the somatic peripheral distribution of the affected nerve or nerves

Sympathetic pain is really a transferred pain with the distinction that in sympathetic pain a painful sensation is present in the organ originating the pain, whereas in transferred pain there may be no painful impression or sensation in the region or organ in which the pain originates.

Projected pain is felt as being present either in a part that has no sensation (as in locomotor ataxia) or in a part which, because of amputation, no longer exists.

Reflected (deflected or reflex) pain is that pain in which the stimulus is carried to the sensory ganglia or to the cord and then is transferred from the sensory filaments of the neuron primarily affected to those of a secondary neuron. The stimulus

When a patient has a disorder induced by the physician through auto-suggestion based on the physician's examination or manner of discussion of the disorder, it is designated as an *iatrogenic disorder.* A patient may have a disease or disorder induced by the technical procedures employed by physicians and specialists in examinations, medications, or operations; these conditions are designated *iatrotechnical diseases or disorders.*

Experience teaches that each topographic area of the body and each system of the body is liable to iatrogenic disorders or iatrotechnical disorders For instance, locomotor disorders may be induced by the prolonged application of appliances, even if properly fitted Improper fitting of appliances may be disastrous, as illustrated by Volkmann's ischemic paralysis. The use of unnecessary arch supports or the transfer of arch supports from one pair of shoes to a second pair of a different size or last is a common cause of complaint.

The application of appliances, for instance, a stiff heavy back brace for a fatigued back without significant organic disease, may originate a serious disability in a hypersensitive patient.

A bunion operation in an occasional instance may leave a hypersensitive, painful scar just as disabling as the original bunion and thus create an iatrotechnical disorder.

Inquiries by a physician regarding the complaint of cough in association with expectoration, hemoptysis or shortness of breath may initiate these symptoms for

drip fixes the disorder of sinus trouble in the patient's mind, and the postnasal drip is complained of as sinus trouble.

The recognition of the complaints indicative of hyperventilation and that of sighing respirations is more essential in many instances than the recognition of some such condition as a mild pulmonary emphysema If a patient has one of these syndromes, it should be made clear to him that he has an insignificant illness resulting from a nervous tension and not disease of the lungs which prevents the entrance of a sufficient amount of air into the lungs

Perhaps there is no disease any better known and more dreaded by most intelligent patients than is pulmonary tuberculosis At times extensive study and observation may be required in order to determine whether or not the reinfection type of pulmonary tuberculosis is present. If there be indeterminate symptoms present, whether or not these are the result of an active pulmonary tuberculosis, care is exercised lest the suggestible patient become overly concerned before an active pulmonary

the physician in explaining an irritative neurogenic cough, by the time the patient reaches home after having pondered the questions and the examinations made by the physician, often an entirely erroneous conclusion is reached of what has been said The patient reasons that so many questions would not have been asked and so many examinations would not have been made just to explain an inconsequential cough There is no way for the physician to avoid these reactions in his patient except to recognize so far as possible the reactions of certain individuals and avoid any suggestive remarks concerning the organic bases for the complaints until sufficient objective data have been obtained or such data cannot be had.

of c
for

to possess an average of greater sensibility to pain than those of Teutonic or Slavonic groups. The important variations, of course, are personal or individual. The neurotic patient of any racial group will complain bitterly of pain from a cause which should not give rise to more than simple discomfort The pain suffered by the abnormally sensitive person, however, is as real and existent in the consciousness as the slight discomfort felt from the same cause by a person given to less verbosity. The pain suffered by an abnormally sensitive individual, even though such pain in a normal subject might not be considered severe, is quite as disabling as a more severe pain in a more stoic individual.

Manner of life and occupation probably do not modify susceptibility to pain. The habitual endurance of hardship teaches the realities of life and trains the individual in the methods of proper evaluation of pain Conversely, the person guarded from rude mental or physical contacts and not accustomed to discomfort and pain, may feel that moderate pain is unbearable. A strong mental prepossession, such as religion, or excitement over an accident, may interfere temporarily with the registration of painful impressions on the consciousness Sensibility to pain is likely to be increased by its long continuance, and it is a common observation that each recurrence of pain during the course of a disease finds the patient less able to bear it. Fright or expectant apprehension invariably increases pain and sometimes originates it.

Complaints Referable to Iatric Disorders. The impression is often gained from eliciting the complaints of patients that they have got the terms, definitions and expressions used in descriptions of their discomforts from observation or discussion with others who are sick or ailing In some instances they have acquired their terminologies from physicians.

Information, terminologies and misinterpretations gained from talking to relatives, friends or other patients are not nearly so serious as those obtained from physicians or from others who administer to the sick and indigent When a patient goes to a physician, this act is in itself an expression of confidence in that physician. Whatever the physician tells the patient, the patient believes in most instances Since the patient believes the physician, this places a responsibility on the physician to mark his words when discussing a patient's disease or diagnosis with him.

Honesty is moral soundness: rectitude is that integrity chiefly applicable to social transactions, *sincerity is honesty of mind or intention*. The fact that patients are honest and sincere in their belief that they have physical complaints that can be rectified by injections, treatments or surgical operations does not in itself justify the performance of such procedures It is unfortunate that the carrying out of therapy by some practitioners of the healing arts, honest and sincere but not thoroughly grounded in the scientific principles of medicine and surgery, has subjected patients unnecessarily to injections for toxic conditions and to surgical removal of appendices and gallbladders and, in women, of the internal genitalia.

It is appropriate here to quote from Oliver W Holmes. "There is nothing men will not do, there is nothing they have not done to recover their health and save their lives. They have submitted to be half-drowned in water, and half-choked with gases, to be buried up to their chins in earth, to be seared with hot irons like galley-slaves, to be crimped with knives like codfish, to have needles thrust into their flesh, and bonfires kindled on their skin, to swallow all sorts of abominations, and to pay for all this, as if to be singed and scalded were a costly privilege, as if blisters were a blessing, and leeches a luxury. What more can be asked to prove their honesty and sincerity?" (*Medical Essays*, Boston, pp. 378, 379)

Patients who have a heightened threshold for suggestion may become either alarmed or highly pleased at the suggestion of a particular diagnosis. In either case, what the physician has said about the diagnosis of a certain train of symptoms may create in the patient's mind a permanent disorder or an erroneous belief about the disease or disorder from which he suffers.

may be told by the physician that his fatigue may indicate some organic disease Specialists in the diseases of the chest have emphasized the importance of fatigue in early pulmonary tuberculosis to the extent that the term fatigue is firmly associated with this disease. However, fatigue is common in low-grade infections and more especially in the psychoneuroses

It is true that organic disease may be overlooked and the patient treated for functional disease, but the reverse is more often true and frequently more disastrous.

When surgical operation is indicated for organic disease in the presence of functional disorders, explain to the patients the difference between the two and do not leave the impression that repairing the lacerated perineum, cauterizing the cervix, suspending the uterus, removing the gallbladder or the appendix, is going to restore to them a stable nervous system. The surgeon is too often pleased by the temporary relief due to the rest in bed following operation, and by the diversion of patients' minds from their troubles to their operations Unfortunately the relief thus obtained is not lasting.

As has been stated, iatrogenic and iatrotechnical disorders may occur in any topographic region or system of the body. Physicians try to prevent them. One helpful way in preventing them is to realize that the patient may be wrong in the report of what the foregoing physician has said or done.

Concluding Remarks in Regard to the Complaint. In an occasional instance it may be wise for the physician to disregard the initial complaint of the patient and to follow through chronologically each and every departure from health to the present time and then make his own conclusions how best to proceed

THE HISTORY: ANAMNESIS

In the elaboration of the complaint much time, as has been indicated in the foregoing discussion, may be necessary in obtaining the *what, when, where* and *why.* The *what* is the concept of the patient of the cause of the initiating factors of the illness, the *when* is the time sequence of the events, the *where* is the position of the patient in relation to place and person, and whether or not the patient was affected inwardly or outwardly by the environment Environment here means the surrounding conditions, influences or forces The classification of the what, when and where constitutes the *why,* and thus is the history

The history arbitrarily is divided into the present illness, the past illnesses, which may or may not pertain to the present illness, and the family or genealogic history, which likewise may or may not pertain to the present illness. A classification of the attestations of the nature and purposes of the complaint may embrace all of the arbitrary divisions of the history but usually only the present illness.

Before one begins the recording of the history, it is well briefly to relate the complaints back to the patient and ask for corrections and elaborations. If the events and complaints can be quickly verified by the patient, the first definite piece of diagnostic information is at hand, the complaints are based on organic disease If the patient heckles and makes many changes in and additions to the complaints when they are related back to him, likely the disease or disorder is of functional or nervous origin. Thenceforward the physician questions in his own mind the validity of all assertions and complaints the patient may utter

The History of the Present Illness. The complaints having been obtained, the present illness can be separated In most instances the present illness is but an elaboration in sequence of the origin and development of the complaint or complaints.

During their training, medical students commonly are admonished that in practice the physician must obtain a full and careful history in each case. A full and careful history may not be obtained in some instances on one survey of the illness. It is obtained or, rather, built up by repeated attempts often extending over days. Emphasis may change when the patient has had time to ponder the questions asked.

ries a severe social disapproval. A physician who remarks to a self-conscious patient that "you may have syphilis" may create a disorder more serious than syphilis itself. (2) False positive serologic reactions The treatment of false positive serologic reactions by antisyphilitic therapy often creates a serious iatrotechnical disorder (see False Positive Serologic Reactions, Chapter 17)

Iatrogenic heart complaints and disorders may be found to have originated from the statement of some life insurance examiner or physician to the effect that the heart shows some abnormality such as a murmur or irregularity of rhythm as revealed by the electrocardiograph; or else from the rejection of the applicant for life insurance on the score of some heart disturbance or of high blood pressure. Sometimes it is a mere assumption on the part of the applicant himself that the heart must be diseased because two or three examiners were called in to listen to it In a person of the appropriate mental composition, the slightest suggestion that the heart is not intact may be enough to start a myriad of emotional reactions, which are very difficult to subdue if the patient has a relative or friend who happens to succumb suddenly to a coronary occlusion

An individual may have forgotten, for a long time, the remark of a doctor about some minor abnormality in the heart action until there appears some symptom which calls the attention of the patient to the heart and renews the doubt that might have once existed as to its integrity The renewed interest in the action of the heart may be created by a sudden skip or a twinge of pain, or may be merely what is regarded as undue palpitation or dyspnea after some special exertion. Such disturbing symptoms are often first noticed during convalescence from an illness

In eliciting the complaints of patients it is not to be supposed that organic heart disease is found only in individuals who have stable minds and nervous systems Organic heart disease does occur in those whose mental make-up predisposes them to apprehensions and fears These patients will have a tendency to complaints explainable on the basis of organic heart disease and too there will be complaints and symptoms which cannot reasonably be ascribed to the heart disease present However, when a structural disease is itself causing severe or distressing symptoms, the neurotic symptoms, if present at all, are likely to be relatively unimportant It is in the milder forms of heart disease, with few or no real symptoms, that the complaints due to emotional reactions tend to occupy the foreground. A correct differentiation between the complaints which are the legitimate result of the existing organic disease and those which are merely the expression of the associated psychic upheaval demands skill, judgment and experience Experience and common sense dictate just what is to be expected in the way of symptoms from the type and grade of the organic lesions present in order to recognize that certain of the symptoms have no direct relation to the somatic disease

This association of organic disease with complaints of a purely neurotic nature is encountered in cardiac patients of almost all ages Older children who have rheumatic heart disease have been taught by an overanxious mother or physician that all physical effort is to be avoided They complain of what they have been taught to expect if exercise is attempted Neurotic women who have long-standing but relatively mild mitral stenosis and persons in middle life who are oppressed by the knowledge that they suffer from high blood pressure may be full of complaints given to them by a physician, the physician having diagnosed their heart disease by means of an electrocardiogram Physicians, some of them, are much too prone to regard physical overexertion as the most serious hazard to which cardiac patients are exposed, and to fail to give proper weight to the potentialities for harm that reside in violent psychic stimuli and prolonged sedentary habits

Iatrotechnical disorders and complaints often arise from the treatment of a patient for functional disorders as organic disease. The patient is submitted to unnecessary medical and surgical treatment, thereby intensifying the neurosis. Such a patient

disease cannot be overestimated Each symptom should be elicited and the time of its appearance correlated with the chronology of the other symptoms

The statements of patients with reference to the therapeutic agents used by physicians previously consulted are ordinarily untrustworthy. If such knowledge can be obtained from authoritative sources, however, it may be of considerable value. Thus certain symptoms, otherwise unaccounted for, may be explained as due to the administration of certain drugs.

The Past History. The past history includes information about the patient, the age, sex, nationality, occupation, places of residence, habits, experiences, sensations and previous diseases or injuries Such considerations embrace also the chronologic occurrence, seasonal or diurnal, of certain diseases, and the comparative infrequency of others. These incidents are first entered in outline form and later translated chronologically as the history is written for permanent record.

AGE. Anatomic structure varies with age, and physiologic processes have peculiarities which are characteristic of different periods of life. Moreover, the effects of environment, occupation, habits, the beginning and end of sexual life, and the wearing out of the organism are manifested at varying ages. Consequently there is a distinct preponderance in the frequency of certain diseases or classes of disease at special age periods. The diseases of youth are often the direct progenitors of those of old age, and the life of the individual may be a constant struggle with disease of hereditary origin or with disease that began in prenatal life

SEX. Putting aside the diseases due to differences in structure and function between men and women, there remain certain maladies which have been said to occur more frequently in one sex than in the other. These discrepancies are attributable mainly to manner of life and in women to disabilities incident to gestation Men have been said to suffer especially from diseases induced by exposure, by hard physical or mental work and worry, and by the acquirement of injurious habits. Women, more commonly than men, lead an indoor life, and many are harassed by household worries and domestic anxieties which create a special environment. In the diagnosis of disease, statements concerning differences in habits of men and women are of minimal value

RACE. The susceptibility to disease, or its opposite, immunity, possessed by certain races has caused much comment. Often the data presented favoring racial immunity or susceptibility are not convincing, for there have not always been clear definitions of the term race The terms race and nationality are not always synonymous (see Races, Chapter 16).

OCCUPATION In considering the effects of occupation in causing disease, it will be found necessary to ascertain the nature of the patient's employment, whether active or sedentary, and whether or not the work requires handling of injurious tools, or handling of toxic or irritating substances or inhaling them Hobbies, habits, and contacts with animals are details a knowledge of which may be useful. Previous occupations should be ascertained The state of health sometimes enforces the occupation

RESIDENCE. Knowledge of the place of the patient's residence may be of considerable importance, if not with regard to diagnosis, at least with regard to prophylaxis of future attacks. In the diagnosis of the fevers the fact of the patient having visited or lived in countries or localities where these diseases are prevalent may furnish a clue otherwise lacking Malaria, hookworm, fungi and rickettsial disease are examples of diseases which have at times special affinities with certain localities.

Other items embraced under the head of residence concern the effects of climate, of residence in city or country, seashore or inland; and the sanitary condition of dwellings with reference to ventilation, drainage, heating, cleanliness, water and food supply and the availability of sleeping nets for protection from insects.

HABITS The habits formed by individual persons are interwoven with age, occu-

Likewise the recorder of the history will desire to inquire about other happenings, after time has passed. He tries first of all to get all the complaints arranged according to the systems from which they originate; in generalized disease he attributes them to the body as a whole; emphasis then will usually be obvious.

The historic data having been arranged according to topography or to the system of origin, the etiology, if not already evident, is sought In obtaining data pertaining to etiology, direct interrogation is necessary. It is mandatory to reduce the number of etiologic possibilities to a minimum In making this reduction, it is well to realize that the etiology of all diseases has been categorized in the various nomenclatures of diseases into (1) diseases due to prenatal influences, (2) infections, (3) intoxications, (4) trauma or physical agents, (5) diseases secondary to circulatory disturbances, (6) disturbances of innervation or psychic control, (7) disturbances of static mechanical abnormality, (8) disorders of metabolism, growth or nutrition, (9) new growths and (10) those diseases in which structural reaction is manifest, but the cause is unknown Some hereditary and familial diseases belong in the last category.

It would be repetitious to give here in greater detail than the foregoing outline the reasons for placing any particular disease or condition of topography or system in a certain etiologic category, for that is the object of the text of this book

It is well to realize that in obtaining the history the largest drafts are made on the tact of the physician, and it is during this time that the important relationships between physician and patient are being established The physician is not a proselytizer, the right of the patient to his own religion and morals is granted Success depends to a great degree on true friendliness, on mutual confidence and, essentially, on correct mutual understanding of the spoken word

The patient may be one of the odd persons from whom it is difficult to extract more than a monosyllabic answer, or he may be so talkative that a question can be slipped in by the physician only when the patient pauses to breathe Dense ignorance may be an obstacle, so also may shame or false modesty Exaggeration of symptoms, a too common failing, must be quickly recognized and likewise the opposite, a stoic pride in making light of symptoms and disability. These and other difficulties, for example malingering, require the exercise of skill in the art of cross-examination and diplomacy

Except in the case of suspected malingering, when the answer may flatly contradict the alleged condition, leading questions are to be avoided, especially with impressionable or ignorant patients For instance, it is better to say, "Did you have any pain in the head?" than "You had pain in the head, did you not?" The first question is a simple interrogation, which may elicit a reply of "Yes" or "No" The second almost forces the answer "Yes" Care is to be taken lest the patient's story should be too narrowly limited, otherwise a knowledge of important symptoms may not be gained. It is well to expend additional time and patience and, if required, to lower questions to basic or even to depraved linguistic levels, in order to make sure that a possible vital point in the history is not missed.

An important point, with reference to early diagnosis of a host of diseases of infectious origin, is to learn of any known exposure. Another important diagnostic aid is information about fatigue of mind or body, dietetic imprudences, toxic agents, and chilling of the body or taking cold This last factor is frequently assigned by patients as a satisfactory etiologic explanation of the most diverse ailments.

A definite statement of the time of onset will generally place the disease in one of two categories, acute or chronic As a rule, acute diseases begin suddenly, whereas chronic maladies may continue over a long period before the symptoms force themselves on the attention of the patient.

The manner of onset should be accurately ascertained by separating the symptoms which initiated the attack from those which appeared at a later period. The value of a strict chronologic history of the symptoms which succeed the onset of any

ing diseases, in their prognosis or as suggestive in regard to their possible occurrence in a given case: deficiency states, myocarditis, cirrhosis of the liver, chronic pharyngitis, chronic gastritis, delirium tremens, neuritis and Korsakoff's disease.

The Family History. The family history of the patient is of much importance because of the light which may be cast by it, not only on the present illness, but also on the constitution and tendencies of the patient.

It is not always possible to obtain a complete and accurate family history. It is usually necessary to cross-examine the patient with some particularity, inquiring into the symptoms and duration of illnesses attributed to ancestors, and bearing in mind the approximate meanings of various common terms. For instance, old age is frequently assigned as a cause of death from the age of 50 years or more and is a term which has little meaning. In many instances in which childbirth is assigned as a lethal cause, death is found to be due to some other cause.

Inquiries regarding certain diseases should be made cautiously because of the possibility of arousing feelings of shame or fear. If it is apparent that shame and fear exist, it is better to ask about the symptoms without mentioning the names of suspected diseases such as syphilis, tuberculosis and cancer. A feeling of reproach to family or personal pride in acknowledgment of the existence of certain ailments may lead the patient to conceal important information.

A full statement of the family history includes the nature of the illnesses (with the age of the living) and the causes of deaths (with the age at death) which may have occurred among the patient's parents, paternal and maternal grandparents, brothers and sisters. It is requisite at times to ascertain similar facts with reference to aunts, uncles and cousins. It should be borne in mind that transmissible tendencies may pass over one generation and may be sex-linked Also it is just as important to know, and to inform a young couple whose first child is born defective, that malformations are often sporadic. In an isolated case of a congenitally defective child in a known normal genealogic history there is no reason to suspect that subsequent children will be abnormal Occasionally, however, contributing factors can be discovered if the basic information is at hand. In general, the study of the causes of congenital malformation has yielded definite knowledge concerning some causative factors It may be pointed out that German measles (rubella), toxoplasmosis and irradiation are known causes of congenital malformations.

COMMENTS

While discussing the complaint and the history, the physician forms a conception of the mental characteristics of the patient, in health and as modified by disease. As a rule, the more highly trained the mind, by private study or at college or in business, and the more elaborate and complex the social environment, the greater is the necessity for an appreciation of the personal traits of the individual. Influences which produce no apparent effect on some laborers, toughened by hard life, will cause profound perturbation in the somewhat hyperesthetic person, man or woman, whose nervous system is in a state of tension from the demands of family, society, art, literature or religion

If necessary, information may be obtained from friends or relatives concerning the mental traits of the patient in health, but such information should not be accepted without proper consideration of its source. Inquire especially as to the existence of extreme susceptibility to pain and of exaggeration in the manner of expression; as to whether the patient is or is not easily elated or depressed, or given to undue solicitude about personal health, of himself and of others, and other points which may be serviceable in estimating the value of the statements made by the patient or the present deviation from the normal mental and physical health. Such inquiries should be made with circumspection and tact in order to avoid misconception of motives

pation and residence. The possible existence of addiction to alcohol, opium, cocaine or other drugs is always present. Diet; the use of tea, coffee and tobacco, clothing, sleep and exercise are largely governed by the social condition and environment Both men and women should be interrogated as to the amount and strength of tea and coffee taken daily. The tea-and-cake habit is mainly found among women. The examiner should ascertain also the kind and amount of alcoholic beverages taken and the time of taking; that is, whether before, during or between meals; and how much tobacco is used, of what kind, and in what manner (with reference to nasopharyngeal catarrh, nervousness and cardiac neuroses).

The experiences of an individual depend on many factors, among which are personality, type, and physical stamina The experiences and sensations are recorded only if pertinent to the present illness

Previous Diseases or Injuries. A knowledge of prior illnesses and injuries is of value, provided that their date, nature and severity can be ascertained, for three reasons.

1. An attack of any of certain *diseases renders subsequent attacks of that disease probable* Among such diseases are angina pectoris, apoplexy, appendicitis, asthma, pneumonia, bronchitis, tonsillitis, colics (gallbladder and renal), convulsions (infantile or epileptic), malaria, gout, migraine and neuralgias

2 With many of the epidemic fevers of bacterial, viral and rickettsial origin, a previous attack may negative its subsequent occurrence

3. A *history of the previous existence of certain diseases or injuries may throw light on present conditions* which stand in the relation of sequelae to the primary ailments Examples of these diseases are syphilis, gonorrhea, scarlet fever, rheumatism and chorea, and septic or suppurating foci, leading to subsequent embolic or general inflammations of heart, lungs, liver, pleura, bones, or peritoneum, any or all of them

A history of a fall or other injury may be of some value in arriving at a diagnosis, for instance of a protruded intervertebral disk, jacksonian epilepsy or sympathetic ophthalmia A previous surgical operation may point to the possibility of a recurrence of the condition which required operative intervention

There is little of diagnostic value to be gained from the varying statistics of the *seasonal prevalence of disease* in the United States, beyond the broad statement that diarrheal diseases predominate during the summer months, and poliomyelitis in late summer, whereas pulmonary disorders and rheumatic affections are most prevalent in the winter and early spring Zymotic diseases occur in largest number during the cold season, but this is to be explained rather by the opening of the schools and the closing of house windows than by the effect of season in itself

It may be mentioned here that certain diseases either begin or show an *exacerbation of symptoms at special diurnal periods.* Bronchial asthma is likely to make its onset or to intensify in severity in the early morning hours; spasmodic croup, as well as diphtheritic stenosis of the larynx, between 10 P M and 12 P.M The suffering from painful diseases is usually worse at night, and in febrile disorders the temperature generally reaches its highest point between 7 P M and 8 P M. The paroxysms of whooping cough are more frequent and severe at night than at other periods The pain due to diseases of the bones, joints and peripheral nerves presents a nocturnal aggravation Pain of rheumatoid arthritis is likely to be worse when the patient arises in the morning than at other times

It is well to remember that some ailments present a more or less regular *periodicity of recurrence.* Among these are neuralgias, migraine, epilepsy, periodic paralysis, relapsing fever, malarial infections, ulcerative endocarditis, paroxysmal hemoglobinuria, pyelonephritis, bronchial asthma and menstrual disorders.

A history of *alcoholism* is important as explanatory of the presence of the follow-

and the charge of making imputations uncomplimentary to the patient. The physician in private practice has favorable opportunity to please and help, because in consulting him the patient has exercised choice in seeking personal advice. The physician in institutional practice conducted by a group or a governmental agency has more difficulty because the patient may not have had a choice of physician.

EXAMINATION

For the general examination the patient is fully undressed of the usual clothing An appropriate dress for the examination is a cape about the shoulders and a sheet around the waist. Many other suitable garments have been devised and all are satisfactory

Manner and Dress. The physician begins to observe the manner and dress of each of his patients as soon as acquaintance is made.

The manner of a patient pertains to the method of performing or executing the ordinary social acts over which custom presides Each individual has a peculiar mode of performing these acts, depending on the training which has been molded by the environment to which he is accustomed. This definition of manner assumes that the individual under observation is reasonably free from physical discomforts and mental stresses. The psychic and physical stresses of illness often change the manners of both men and women For instance, an individual who is suffering from hysteria under normal conditions of life may under the adversities of an additional illness to himself or to a member of his family, behave in a stable and admirable manner An individual of good manners when in health may express a bad manner under the stress of illness and pain in himself or in members of his family.

Modern dress is no longer an expression of status or determinate function There remains a well-developed sense of decorating the body with clothing and accessories such as jewelry and furs. In individual instances it is frequently difficult to differentiate between clothing and ornament, this is especially true of the headwear of women. Cultists with distinctive mental warping may dress foolishly, solely for the purpose of exhibition, justifying such dress by reference to the Scriptures, as, "If I may touch but his clothes, I shall be whole" (*Mark V*).

Although clothing no longer is a symbol of class distinction, it may have diagnostic implication in the individual or in groups of individuals. The most significant implication is related to the sexual representations or aspirations of the female During the last 200 years women's dress has changed constantly and alternately in an endeavor to conceal or to reveal the back, breasts, shoulders, arms, legs and thighs During the period of a particular vogue all women, good, bad and indifferent, will and should conform to the fashion The physician is not interested in fashion or in those who conform to fashion, but in those who do not conform. Of definite interest to the diagnostician are two small groups, namely, those who become conspicuous by showing more of the thighs than fashion permits, and those non-conformists who show none of the thighs despite fashion Those who show too many charms are likely to be involved in sexual and marital intrigue or think they might like to be. [illegible] social diseases as well as being [illegible] physically beautiful and deli- [illegible] Those who show none of their [illegible] fected by all sorts of abnormal ergasias.

Of the accessory articles of dress, tinted spectacles, when worn because of "weak eyes" if there is no disease of the eyes, indicate that the wearer admits poor health Excessive and gaudy jewelry, even expensive ornaments of excellent workmanship,

often adorns selfish persons. Perfumes, in profusion, except among Latins, may indicate the absence of the regular use of soap. Distinctive, highly aromatic perfumes are often used by those afflicted with homosexual and heterosexual practices.

In the evaluation of patients with regard to their clothes, the examiner has in mind that with the majority the influence of social customs prevails, as expressed in the Arabian proverb, "Eat what you may, but dress as others do."

An occasional hint may be derived from care of the dress. Omission to use fastenings which may be needed for common decency, the coat or trousers buttoned with the wrong buttons, or a vest soiled with droppings of food may indicate the mental enfeeblement due to psychosis or chronic alcoholism, or due to the physical disability resulting from arthritis or paralysis. Clothing wet and of ammoniacal odor is observed in cases of incontinence of urine and cystitis; when urine dries, it may leave a white deposit on the clothing. A patient may be so crowded and bulging in his clothes as to suggest a recent rapid increase of bulk from obesity or general dropsy. The shoes may be left partly or entirely unfastened from forgetfulness, gout, rheumatism or edema; or slit for similar reasons, or because of corns, bunions or injury; or worn more on one side, or in front, or at the heel, because of paralysis, deformity or disease of the joints

A great deal may be gleaned from the behavior of an individual when asked to disrobe for the examination. A proper amount of timidity at having to undress for an examination is expected of both sexes. Extremes of timidity may interfere with or prevent a satisfactory examination. If the examination is rendered unsatisfactory or impossible, this should be made clear to the patient. Insistence and persistence never accomplish anything Patience on the part of the examiner, with full explanation of the reason for an examination, usually gains the desired results.

During the examination the examiner extends his knowledge and attempts to confirm those things which have been learned from the complaint and the history. He employs his own functions of knowing, combined with his feelings and his strivings, to learn and to demonstrate wherein the trouble lies. He looks (inspection), he feels (palpation), he listens (auscultation), to determine the condition of the tissues. These primary methods of sight, touch and hearing have many applications and combinations, the simplest of which is percussion, a combination of touch and hearing Sight, touch and hearing are the primary methods of examination of the patient It should be realized that native capacity for employing the senses varies with each person. Only a few have the natural capacity of Laennec, Trousseau and Flint, and it is these few who do not argue about the relative merits of palpation, auscultation and percussion versus roentgenologic examination or any other way of objectively demonstrating derangement of tissue by trauma or disease. These few physicians and surgeons who have natural ability do not argue; they are happy to find for themselves the source of disease, or they cheerfully accept the help that anyone or any appliance or other means can give them. Any person endowed with an average degree of the sense perceptions and intelligence can learn the technic of studying and examining patients A lack of acuity of one of these senses may be overcome by constant effort, practice and development of the other senses. For all, it must be known that at least three out of four illnesses are diagnosed and treated from the diagnostic data obtained by the physician from the use of his senses and his knowledge of disease

Theory and Practice of Inspection. Inspection, which is begun with the first sight of the patient, is the most valuable method of examination During the taking of the history the sex, approximate age, race, posture, facial expression, nutrition, color of skin, eyes and hair, and many other details are observed. During any part of the taking of a history and the performance of an examination the examiner requests, "Let me see you do it," or "Show me where the pain originates and where it goes."

The light, preferably daylight when feasible, as a rule should fall directly on the surface to be examined Changes in direction from which the light comes, controlled by moving either the patient or the source of the light so as to permit the rays to fall obliquely across the surface to be examined, are often of value by production of shadows and may accord emphasis of much use in detecting small pulsations or abnormalities of shape and movement.

Theory and Practice of Palpation. Palpation, the use of the tactile sense of the hand and fingers, is an indispensable means of obtaining information in all manners and means of diagnosis. The remarkable extent to which the educated touch may be developed is exemplified in many physicians

In the practice of palpation care should be taken to keep the nails short. The hands should always be warmed before touching the patient. All rough or abrupt pressure is avoided The hand at first should be laid flat on the part, later the fingers and their tips may be employed to determine and localize more accurately any discoverable abnormality When palpating deep-seated organs, or when there is a large amount of overlying fat or fluid, the palpating hand may be usefully reinforced by pressing on it with the other, thus sparing the palpating hand much muscular exertion and leaving unimpaired its power of tactile appreciation

When palpating, the points to be determined with reference to the part or organ are temperature, shape, size, measured (stated in metric terms), consistency; movability, with or not with respiration, tenderness, superficial or deep-seated; fluctuation, the undulation of an enclosed fluid produced by the pressure of the fingers, and appreciated by another finger placed on the opposite side of the enclosing cavity, fremitus, pulsations, thrills or vibrations originating in the heart or blood vessels

The synchronous use of the methods of inspection and palpation is to be encouraged When these are used separately, always look before feeling—and feel before listening.

Theory and Practice of Auscultation. Auscultation may be performed by direct application of the ear to the body or it may be aided by use of the stethoscope Auscultation may be combined with inspection and palpation (see Diseases of the Respiratory System, Chapter 9)

Directions and Topography. In the examination of patients directional terms for description of findings are employed constantly, and it therefore is important to use the proper terms that do not permit confusion. Such terms as *front* and *back*, *top* and *bottom*, are not desirable For the trunk, *dorsal* and *ventral*, *cranial* and *caudal*, are the proper directional terms, but are not generally employed, *anterior* and *posterior*, *upper* and *lower*, *apex* and *base*, are the terms in use, though they may admit of confusion *Dorsal* and *ventral* are permissible, but not wholly admirable, terms applicable to the inferior extremity and the upper arm as well, for these aspects are constant in orientation with the trunk. The terms *superior* and *inferior* are so firmly entrenched in diagnostic descriptions, particularly in connection with aspects of the vertebrae and as names of structures (as M. serratus posterior superior), that they cannot be abandoned The term *superior extremity* is diagnostic and almost always is used instead of the more correct designation, *pectoral extremity* The meaning of *anterior* and *posterior* when applied to aspects of the ankle is likewise clear, but when applied to the wrist, it is not clear, for the wrist is reversed in pronation and supination In designating aspects of the wrist, *dorsal* and *volar* (*or palmar*) are the proper terms

Cranial and *caudal*, though technically proper terms for the aspects of the head, are clumsy. The head of man is oriented on the same axis as that of quadrupeds, and *anterior* and *posterior*, *superior* and *inferior*, are permissible terms. *Lateral* and *medial* directions in the upper arm and in the inferior extremity may be used, although *fibular* and *tibial* in referring to sides of the lower leg and the foot are prefer-

able. *Lateral* and *medial* directions are objectionable for forearm and hand because it is not known whether the natural or the anatomic positions are meant. For these, *radial* and *ulnar* directions are correct.

Directional terms of a general nature, in antithetic pairs, are as follows (based on Howell's *Gross Anatomy*, D. Appleton-Century Co, 1939):

Anterior and *Posterior*. front and back, respectively; properly used for the head only, but permissible at times, because of established usage, for the trunk. The proper corresponding terms, except for the head, are the following:

Dorsal and *Ventral:* The term dorsal indicates the back, the entire back or upper side of an animal when the ventral surface is down. Dorsal is incorrectly used to designate a particular segment of the back, for instance that of the thorax. Likewise ventral is not for the front of the thorax. The thoracic vertebrae are often incorrectly designated dorsal vertebrae. Since vertebrae are identified according to the region of the back to which they belong, for instance as cervical, thoracic, lumbar, sacral and coccygeal it is incorrect to designate any of them as dorsal vertebrae. They are thoracic vertebrae In instances of increases over the usual number of vertebrae in a particular region, the extra vertebra is designated by addition to the usual number for that region, for instance a sixth lumbar vertebra. The dorsal aspect of the limbs, both upper and lower, is the part covered by the dorsal or extensor musculature. The dorsal aspect of the arm is the back of the upper arm, back of hand and wrist and the corresponding aspect of the forearm. The dorsal aspect of the inferior extremity is the front of the thigh, leg and upper part of the foot.

Dorsal and *Volar* (or *Palmar*): the proper terms for back and palm, respectively, of hand, and corresponding aspects of forearm.

Dorsal and *Plantar*. the proper terms for upper aspect and sole respectively, of the foot.

Superior and *Inferior:* permissible but less desirable (except for head) alternatives for cranial and caudal.

Cranial and *Caudal:* the proper terms for the indicated directions in the trunk.

Superficial and *Deep:* superficial is nearer the surface (from any aspect), as opposed to deep.

Medial and *Lateral:* medial is toward the median plane, and lateral is toward the side.

Peripheral and *Central:* peripheral, toward the periphery, central, away from the periphery. Used mostly in connection with the nerves.

Proximal and *Distal:* proximal, toward the median plane; distal, away from the center. Used mostly in connection with the extremities and the alimentary tract. In the alimentary tract proximal is employed to designate nearest to the mouth or to the beginning of the segment, irrespective of topographic situation. For instance, *proximal jejunum* indicates that part nearest to the stomach or the mouth even in the presence of situs inversus viscerum In the alimentary tract, particularly the intestines, *distal* indicates away from a designated point. It is used in opposition to proximal. Common use of these terms is in connection with artificial stomas; for instance, proximal stoma, the one which discharges the intestinal dejecta. *Distal stoma* designates the direction in which the intestinal contents would or do flow away from the stoma

External and *Internal* used chiefly to indicate respective surfaces of hollow organs, or of the body as a whole.

Radial and *Ulnar* the proper terms for denoting the sides of forearm, wrist, and hand; toward the radius and toward the ulna, respectively

Tibial and *Fibular* the proper terms for denoting the sides of the lower leg, ankle, and foot, toward the tibia or toward the fibula, respectively.

The following terms in frequent use might prove confusing unless explained:

Mediad: toward the median plane.

Medius: middle; between dorsal and ventral or between external and internal

Intermedius: between medial and lateral.

Transversus: transverse to a particular part of the body.

Transversalis: transverse to the body axis.

Transversarius. relating to some structure which is transverse (as Mm. intertransversarii, the muscles between transverse processes).

As the body is three dimensional, so there are three planes of the body:

Sagittal Plane: the dorsoventral longitudinal plane; through or parallel to the sagittal suture.

Coronal or *Frontal Plane:* the longitudinal plane, from side to side, at a right angle to the sagittal suture; through or parallel to the coronal suture.

Transverse Plane. the horizontal plane, at any level, at right angles to both sagittal and coronal planes.

Anatomic Regions. The primary regions of the body, as discussed here, comprise *head* (caput), *neck* (collum), *back*, and *superior* and *inferior extremities*. Each of these is customarily divided into secondary surface regions. The boundaries of some of these are not always to be determined with accuracy by one inexperienced in anatomy, for the reason that their extent usually depends on some subsurface feature Anyone interested will find by reference to the *Basle Anatomical Nomenclature* (B N A) list of regions, that many of the secondary regions (as parietal, frontal, deltoid, posterior femoral and the like) are self-apparent, and that some other terms are of but little use in diagnosis

In this text each of these regions is described in association with the topography and topographic diagnosis when that particular region is being considered. Generally the requirements of the *Basle Anatomical Nomenclature* are at least respected and partially fulfilled.

TOPOGRAPHY AND REGIONAL DIAGNOSIS OF DISEASES OF THE HEAD AND ORGANS OF SPECIAL SENSES

The general practitioner and the internist are not expected to make specialized examinations and diagnoses or to carry on specialized treatment. However, they are required to have sufficient knowledge of diseases described and diagnosed by the specialist to discuss intelligently with the patient the diagnosis and treatment which the specialist suggests in the individual case. In the discussion that follows, it is hoped that there is information which may be of some help to the physician in his fulfillment of his obligations to the patient.

The head varies in shape and size according to race, sex and age. As a rule, the head of a man is larger than that of a woman. The head tends to change shape and increase in size with age. If the head enlarges out of proportion to the rest of the body, the condition is designated as *macrocephalia*. If the enlargement tends to produce mainly a broad head, the condition is designated as *brachycephalia* If the enlargement tends to produce a conical-shaped head, the condition may be designated as *oxycephalia*. If the head is unusually long from front to back, the condition is known as *dolichocephalism* If the head is unusually narrow, the condition is designated as *stenocephalia*, if the head is unusually small, as *microcephalia*, and if the head is generally distorted and of abnormal shape, it may be designated as *plagiocephalism*

In many men past middle age an increasing prominence of the supra-orbital ridges develops, with the result that the eyebrows seem to overhang the eyes more and more and the countenance looks different from what it did 10 or 20 years earlier. This enlargement is due to or is associated with enlargement of the air cells of the frontal sinuses and is not pathologic However, if this enlargement of the forehead is excessive, it must be distinguished from acromegalia and from another condition, of no clinical significance, formerly designated leontiasis. Leontiasis may or may not be associated with a thickening of the frontal bone which is known as benign frontal exostosis, this too is of no clinical significance. Often a patient who has enlargement of the forehead seeks medical advice with the complaint that he has noticed that the size of his face is increasing; such a patient nowadays wonders whether or not he has disease of the pituitary gland. The condition can be distinguished from acromegalia in that rarely in acromegalia is the frontal bone alone affected, and more often the affection of the forehead is much slighter than the increase in the size of the lower jaw and the phalanges of the hands and feet Tumors of the frontal bones almost always cause an asymmetric enlargement

Changes of Shape and Contour of the Head in Disease. In certain diseases characteristic changes in the size and contour of the head and face are of diagnostic importance

In *hydrocephalus* the head is abnormally large and usually globular, sometimes pyramidal, in shape Hydrocephalus is most frequently observed in infants and children. An abnormal increase in the measurement of the head is the principal symptom by which chronic hydrocephalus can be recognized Aside from the en-

largement the most characteristic feature is the prominence of the forehead at the root of the nose The rachitic head may resemble a hydrocephalic head. Many children recover from mild degrees of hydrocephalus. The only evidence of it left in adulthood is an increase in the size of the forehead which gives the appearance of a rather large dome-shaped head

Heads deformed by *rickets* and changes of the head produced by sporadic *cretinism* or *myxedema* are described in appropriate places in subsequent chapters.

If the face presents an appearance as if it were composed of lateral halves from two different individuals, with the vertical line of junction sharply defined, and if the hair of the smaller side is thin or absent, the eye sunken and the skin altered in appearance, it is probably an instance of facial *hemiatrophy*

If both sides of the face appear normal but one is much the larger, the condition known as *congenital hemihypertrophy* should be suspected. Along with congenital hypertrophy, hemangioma of the skin over the affected regions often is present. Since congenital hemihypertrophy often involves one half of the body, confirmation of congenital hemihypertrophy should be sought by making comparative measurements of the arms and legs The arm and the leg which are hypertrophied may be on the same side as the hypertrophied half of the face or they may be on the opposite side

Facial asymmetry may exist also with congenital torticollis or wryneck. If the cranium is enlarged and globular, and the malar prominences are marked and the orbital rims massive, the presence of hyperostosis of the cranium should be suspected

The tuberous growth of *leprosy* occurring on the face, together with the resulting ulceration and cicatrization, slowly changes the shape and contour of the countenance, which assumes the so-called leonine aspect or facies leonina

Tower-shaped skulls are rather characteristic of some of the congenital anemias (see Hemic Diseases, Chapter 11)

Abnormal Movements of the Head. *Nodding spasm* is a rhythmic nodding movement of the head In children this movement may be a form of habit spasm or of epilepsy In cases of epilepsy or convulsive disorders nodding spasm is accompanied by a momentary loss of consciousness. It may occur in hysteria, either alone or as a part of the so-called *hysterical chorea*

Pulsating shaking of the head, which occasionally is seen in the aged, is not necessarily evidence of senility or arteriosclerosis. It seems at times to have a *hereditary factor It is often found in postencephalitis* or Parkinson's syndrome.

Spasmodic torticollis is a spasmodic jerking of the head which recurs every few minutes. In the chronic form of the disorder the head is brought toward one shoulder, which may be simultaneously jerked upward to meet the head at the same time that the face is rotated to the opposite side and the chin is raised. In chorea, as contrasted with spasmodic torticollis, the movements of the head are extremely irregular and bizarre, and the facial muscles are affected before those of the neck. Torticollis is often a form of conversion hysteria

Inability or disinclination to move the head, especially if the patient is prone to support it by hand, may be due to disease of the cervical vertebrae. If this manifestation is associated with dysphagia, it points to disease of the articulation between the atlas and the occiput.

Retraction of the head of a bedridden patient—that is, a drawing back and *fixation* of the head by contraction of the posterior cervical muscles so that the occiput bores into the pillow—is a symptom in all forms of cerebral and cerebrospinal meningitis, particularly when the disease is affecting the basal meninges It is seen in tetanus and in strychnine poisoning as a part of the general tonic spasm.

Other causes of abnormal fixity of the head are occipital cervical myalgia and cervical arthritis, swollen and painful cervical lymph nodes, sprain of the cervical muscles or other traumatism of the neck, postpharyngeal abscesses, congenital and

spasmodic torticollis, and contracted cicatrices, especially extensive scarring from burns

THE SCALP

The *skin* of the scalp is the thickest in the body, although not so dense as that of the heel. Besides the hair follicles, the scalp contains abundant sweat and sebaceous glands and blood vessels, which are associated with the hair follicles

The *hair* of the scalp is to a very slight extent an index to the general robustness and vigor of the individual Thick coarse hair is at times associated with strength of constitution, and scanty fine-textured hair with a delicate habit of body, but there are many instances in which this is not the case. There is some diagnostic value in an observation of the color and scantiness of the hair (see page 1197).

Loss of Hair Color. Graying of the hair, the physiologic loss of the pigment of the hair, begins in the average individual at 40 to 45 years of age and slowly increases as the years pass. Early grayness is not always a sign of premature old age and is not necessarily associated with degenerative arterial changes Gray hair is compatible with good health and otherwise normal tissues. The loss of color is frequently dependent on a hereditary factor.

When chronic poisoning is suspected, if it is apparent that the hair is dyed—and dyeing usually is apparent—it may be an important clue in the diagnosis (see Hair Dyeing, Chapter 19).

Alopecia (Acomia, Calvities, Baldness) The etiology of alopecia is not often obvious Congenital baldness (alopecia adnata) is rare. This is usually associated with defective teeth and nails. These two conditions are of little practical importance diagnostically.

Premature Alopecia. This is an exceedingly common condition, especially in men It is endocrine in origin; eunuchs are never bald. It is not attributable to modern civilization or to the wearing of tight hats It is familial in origin and common to all races of men

Premature alopecia begins at about the age of 20 years and is often completed by the age of 30 years, only a rim of hair being left at the back and sides. Cases, however, do occur in which the loss of hair is more gradual and, even on the vertex, may never become complete The scalp may be obviously seborrheic, or covered with dandruff, which undoubtedly aggravates the condition, or it may look normal

A corresponding type of alopecia occurs in women, but has several points of difference from that seen in men It is more general and is not limited to the vertex, is not so nearly complete, and is more regularly accompanied by seborrhea of the scalp

Alopecia Without Scarring. The etiology in alopecia without scarring is unknown A disturbance in innervation or psychic control is possible In susceptible persons a shock may precipitate an attack, during World War II attacks occurred in three or four weeks after the patients had been torpedoed or bombed. Reflex irritation from neuralgia, a carious tooth, septic sore throat or similar condition has been blamed, but these are not valid causes The patients, even those who have alopecia totalis, are usually in excellent health.

There are several varieties of alopecia without scarring, for instance, alopecia areata, trichorrhexis nodosa and trichotillomania

Alopecia Areata. This common condition is characterized by circular areas of baldness. It is not related to the color of the hair, and it affects men and women about equally In Anderson's experience there was a difference in the position of the primary patch between the sexes. in men it was 60 per cent occipital, 25 per cent frontovertical, in women it was 27 per cent occipital, 56 per cent frontovertical A positive family history was present in 19 per cent, but it is doubtful that this indicates

a familial tendency. Other members of the family were affected at the same time in 6 per cent of cases Vitiligo was present in 4 per cent of cases.

The affected hairs show thinning toward the roots and are easily removed with brush and comb. They may also break off a few millimeters above the skin surface.

Alopecia areata is a relapsing disease, beginning in childhood but more severe between 20 and 29 years of age The hair slowly returns to the bald spots, though it may be delayed for months and may grow back white and remain white. When the disease steadily progresses until all hair all over the body is lost, the alopecia usually is permanent Another resistant form of the disease is that in which the scalp margin is involved in a patchy fashion These patches may coalesce to form a band, giving a wiglike appearance to the rest of the hair.

Nail changes are common in extensive alopecia. When the nails are affected, the changes are usually in the form of rows of tiny pits, as is sometimes observed in psoriasis These pits often are unnoticed by the patient and are found only on routine examination Nails of both the hands and the feet may be affected

Alopecia areata is differentiated from ringworm by the absence of scaliness of the scalp and of fungus in the hairs. Cicatricial alopecia offers no difficulty. Furunculosis is eliminated by the fact that the scar of the original lesion has a center of a red dot

Prognosis is good in ordinary cases for patients less than 40 years of age When there is involvement away from the scalp, for example of eyebrows and the bearded areas and around the edges of the scalp, the lesions are stubborn and persistent Recovery is slow also in cases in which scattered white hairs are present on the bald patches Chronicity is universally a bad omen Alopecia totalis is to be feared in all cases in which the disease lasts more than 18 months.

TOXIC ALOPECIA There are many toxic agents, including roentgen rays and radium, that cause a fall of hair After prolonged fevers the hair may fall Falling hair results from a similar cause during the secondary stage of syphilis (moth-eaten scalp) and after pregnancy After gestation the onset may be sudden and the fall severe In all toxic alopecias an important diagnostic point is that the hair behind the ears can easily be pulled out

TRICHORRHEXIS NODOSA This condition is due to too frequent use of too strong soaps and excessive friction, as may result from a habit of rubbing the hair. The hairs show white nodes which, on microscopic examination, are seen to consist of a splitting of the hair structure so that it has the appearance of having the end worn off

TRICHOTILLOMANIA Trichotillomania is a habit comparable to nail biting Hairs are consciously or unconsciously pulled out The irritation of pediculosis may start the habit An area, or areas, of normal scalp dotted with normal hairs of varying length and a surprising amount of alopecia are the result. The diagnosis requires roentgenoscopic examination of the stomach in search for the possible presence of trichobezoar (hairball)

Alopecia With Scarring. The causes of alopecia with scarring comprise all the etiologic agents producing scarring, such as roentgen rays, radium, burns and infections, such as favus, kerion of ringworm, or lupus erythematosus. The primary cause is usually recognizable The atrophy following the use of roentgen rays or radium is a factitial dermatitis, the scars of burns are deep and contracted; favus has a long history of gradual spread and may still show marginal activity; kerion scars are circular or are combinations of circles; lupus erythematosus may show activity or scarring over the bridge of the nose and medial sides of the cheeks.

Tumors. The scalp contains an abundant blood supply and consequently telangiectasis and venous and cirsoid aneurysms are frequent (see page 316).

There are a number of tumors of the scalp of congenital origin Cephalocele, a protrusion of part of the cranial contents, may be of congenital or of acquired origin.

The cephalocele occurs in the occipital and sincipital regions, either above or below the tentorium. An *encephalocele* is a hernia of brain matter and is covered with the arachnoid; it protrudes through a congenital or traumatic opening in the skull. A *meningocele* is a cystic mass, a protrusion of the meninges, covered by pia mater. A *hydrencephalocele* is a protrusion of a lateral ventricle or of the fourth ventricle covered by brain tissue and the arachnoid.

Dermoid tumors, which consist of occluded ectoderm, occur in the median line of the head and face. They often appear over the anterior fontanel and the external occipital protuberance. Often a thin pedicle attaches the tumor to the dura mater.

Cysts. Sebaceous, epidermoid, inclusion dermoid, and mucous cysts occur about the head and neck.

Cystic skin tumors whose contents consist of keratin are keratomas, and those which are of acquired origin and which contain sebaceous material are sebaceous cysts. Inclusion dermoids are congenital cysts developing along the embryonic lines of fusion and containing hair follicles, sweat glands and sebaceous glands in their walls. Epidermoids are similar in nature to dermoid cysts with the exception that their linings possess no dermal structures.

The wens or sebaceous cysts usually occur in the scalp, and in the lobe and on the posterior surface of the ear. The common tumor of the adult scalp is the sebaceous cyst, which sometimes becomes calcified. Such tumors are usually multiple and are rounded, firm, and though freely movable are invariably attached to the skin at one point, a feature which often distinguishes them from dermoid and epidermoid cysts In the skin overlying many keratomas and sebaceous cysts, there is visible an enlarged pore from which cheesy material can be expressed on manipulation of the growth. There is a wide degree of variability in the dimensions of these tumors; some are scarcely palpable nodules, while others attain a diameter of several centimeters

Keratomas and sebaceous cysts, ordinarily symptomless, are frequently the site of an acute inflammatory process in which the tumor becomes excessively tender and painful and objectively manifests a sudden increase in size When acutely infected, the cyst resembles an acute abscess and exhibits all of the general and local symptoms which attend such a process After an acute infection subsides, a keratoma or sebaceous cyst may resume its normal proportions and appearance. In an occasional case the infection completely destroys the epithelial lining and with subsequent healing the entire cavity of the growth is obliterated. Often an acute infection in one of these tumors becomes chronic, with the result that purulent material is continually discharged externally through a sinus, producing excoriation of the surrounding skin Occasionally one of these cysts becomes chronically infected and then is surrounded by dense fibrocicatricial tissue which may completely mask the true nature of the lesion.

THE FACE

The face embraces the anterior part of the head The bony framework of the face is made up of some of the bones of the skull as well as those of the face proper Deformities and disfigurements of the face which result from injuries or disease or both assume a greater importance to the victims than comparable troubles would elsewhere, for many persons feel that their face is their fortune.

The right and left halves of the face differ from each other and present varying degrees of asymmetry. This facial asymmetry seems to be present in all races In the right half of the face the features are said to be more characteristic of the individual and are more conspicuous than in the left The right eye is more prominent than the left eye, a fact which may be related to right-handedness In the left half of the face the individual features recede.

Malformations. The relatively frequent occurrence of malformations of the face is explained by the complexity of the developmental processes in this region

nerve supply to a portion of the skin. Eating or drinking is accompanied by excessive perspiration in the area in which the nerve supply has been impaired. Langenskiold offered what he believed to be a satisfactory explanation of this distressing symptom, the preganglionic sympathetic fibers governing sweating had been destroyed, thus, according to Cannon's law, the postganglionic cholinergic fibers were rendered hyperexcitable, and during mastication acetycholine elaborated in the parotid gland "diffundated" to the nerve endings in the skin and produced sweating Gustatory asymmetric hyperhidrosis may occur below the neck as described by Mellinkoff and Mellinkoff

THE MUSCLES OF THE FACE

Facial Spasms. Spasmodic contraction of the facial muscles may be tonic, that is, continuous, or clonic, that is, intermittent. It may be unilateral or bilateral and may involve one or all of the muscles which are innervated by the facial nerve In order to form an opinion of the cause of spasmodic affections of the face, it is advisable to take into consideration the age and sex of the patient and to ascertain the presence or absence of disease of the eyes, teeth and skin In some cases the facial symptoms constitute a significant part of a disease of the central nervous system.

The diseases or conditions which may be indicated by facial spasm are mimic spasm, convulsive tic, blepharospasm, nictitating spasm, exophthalmic goiter, chorea, epilepsy, tetanus, meningitis, hysteria, spasm following paralysis, irritation at the root of the facial nerve and, finally, lesions of the cortical center of the facial nerve

Mimic spasm is usually bilateral and ordinarily does not begin until adult age A more or less constant twitching of one side of the face, with partial closing of the eye, occurring in an adult, is a mimic spasm

Habit spasm usually occurs in neurotic children. Characteristically, during the spasm there is a sudden wink of the eye or a rapid drawing of the mouth to one side or a sniff occurring at irregular intervals and greatly intensified in severity by emotional causes

Convulsive tic ordinarily is a hereditary affair occurring in neurotic children. The tic is irregular movement of the facial muscles and frequently those of the arms, and sometimes is accompanied with an explosive ejaculatory utterance of profane or obscene words, or this tic may consist of involuntary repetition of a word or the mimicking of an action

FACIAL PAIN

Infections of the sinuses and the antrums cause facial pain Dental neuritis, particularly when it occurs in senile patients, is troublesome and unfortunately is not readily relieved Often improvement of the general health of the patient by appropriate dietary regimens ameliorates the complaint The *localized dental neuritis* that follows procaine block injections is due to the excessive amount of procaine injected into the immediate vicinity of the nerve The symptoms of paresthesia usually disappear. Postherpetic *ophthalmic neuralgia* is persistent, and its course is not affected by operative procedures. Snake venom may help

The neuralgias are common causes of pain in the face In *glossopharyngeal neuralgia* the pains are projected along the distribution of the ninth cranial nerve. The trigger zone is situated in the tonsillar fossa, and the darting pains are projected toward the ear, usually terminating in the tympanum The pains are precipitated by yawning, swallowing and talking, but not by rubbing the face. The pains resemble those of trigeminal neuralgia in their occurrence, duration, repetition and character, but they differ from those of trigeminal neuralgia in their distribution. In glossopharyngeal neuralgia it will be observed that cocainization of the pharynx will result

in temporary cessation of all attacks, but cocainization of the pharynx will not alter the paroxysms when they are due to trigeminal neuralgia.

Sphenopalatine neuralgia is characterized by boring pain situated in the superior maxillary region. It is most pronounced under the malar bone, and at times extends into the gums of the superior maxilla, the hard palate and downward into the neck. This pain differs from that of trigeminal neuralgia in that it is more or less constant; it is not paroxysmal and is moderately severe, but it is not sufficiently severe to incapacitate the patient unless there is an accompanying neurosis Neither deep injection of alcohol into the branches of the trigeminal nerve nor division of the sensory root affords relief in the treatment of this type of neuralgia.

The trigeminus nerve (trifacial) arises in the medulla oblongata along the floor of the fourth ventricle and supplies motor fibers to the masseters, pterygoid, and the temporal muscles and muscles of the tongue. It furnishes the sensory fibers to the skin of the face (Fig. 4-1) and to the tongue, teeth and the corneae The three divisions of the nerve are designated the ophthalmic, the maxillary and the mandibular.

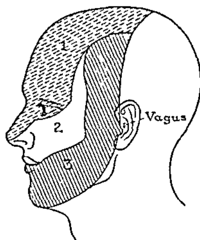

Fig 4-1. Areas within which sensory disturbances and pain may occur in diseases of the trigeminal (trifacial) or fifth cranial nerve 1, ophthalmic division, 2, maxillary division, 3, mandibular division.

Local lesions of the nerve rarely cause severe pain. However, local lesions are often accompanied with impairment of sensation within the sensory distribution of the nerve, for instance in the mouth, loss of corneal reflex or numbness of the skin.

Trigeminal neuralgia (tic douloureux) is of unknown etiology and usually occurs in persons more than 50 years of age. It may occur in an occasional person after the age of 40 years

The chief symptoms are the intense, unilateral, darting pains which radiate from the side of the nose or the upper lip, through the teeth, or into the eye, or even into the forehead and head. The pains come in paroxysms, lasting for a few minutes, during which the face is flushed and the eyes and nose run. There is an expression of agony. The patient, once the disease has started, is seldom free from some pain, and a breath of cold air, speaking, eating or putting out the tongue may bring on a paroxysm The pains may come on for a certain length of time each year, often during the beginning of cold weather.

On examination there may be observed spasmodic movements of the face or jaws There is no disturbance in the functions of the trigeminal nerve in either the sensory or the motor spheres. At the sites where the divisions of the nerves pass through the fascial sheaths, on the upper lip and in the mouth may be observed a so-called trigger point. On stimulation of a trigger point, pain immediately ensues. The employment of ice for the precipitation of pain in one of these patients is a cruel practice

nerve supply to a portion of the skin Eating or drinking is accompanied by excessive perspiration in the area in which the nerve supply has been impaired Langenskiold offered what he believed to be a satisfactory explanation of this distressing symptom· the preganglionic sympathetic fibers governing sweating had been destroyed, thus, according to Cannon's law, the postganglionic cholinergic fibers were rendered hyperexcitable, and during mastication acetycholine elaborated in the parotid gland "diffundated" to the nerve endings in the skin and produced sweating. Gustatory asymmetric hyperhidrosis may occur below the neck as described by Mellinkoff and Mellinkoff.

THE MUSCLES OF THE FACE

Facial Spasms. Spasmodic contraction of the facial muscles may be tonic, that is, continuous, or clonic, that is, intermittent It may be unilateral or bilateral and may involve one or all of the muscles which are innervated by the facial nerve. In order to form an opinion of the cause of spasmodic affections of the face, it is advisable to take into consideration the age and sex of the patient and to ascertain the presence or absence of disease of the eyes, teeth and skin. In some cases the facial symptoms constitute a significant part of a disease of the central nervous system.

The diseases or conditions which may be indicated by facial spasm are mimic spasm, convulsive tic, blepharospasm, nictitating spasm, exophthalmic goiter, chorea, epilepsy, tetanus, meningitis, hysteria, spasm following paralysis, irritation at the root of the facial nerve and, finally, lesions of the cortical center of the facial nerve.

Mimic spasm is usually bilateral and ordinarily does not begin until adult age A more or less constant twitching of one side of the face, with partial closing of the eye, occurring in an adult, is a mimic spasm

Habit spasm usually occurs in neurotic children Characteristically, during the spasm there is a sudden wink of the eye or a rapid drawing of the mouth to one side or a sniff occurring at irregular intervals and greatly intensified in severity by emotional causes

Convulsive tic ordinarily is a hereditary affair occurring in neurotic children The tic is irregular movement of the facial muscles and frequently those of the arms, and sometimes is accompanied with an explosive ejaculatory utterance of profane or obscene words, or this tic may consist of involuntary repetition of a word or the mimicking of an action.

FACIAL PAIN

Infections of the sinuses and the antrums cause facial pain Dental neuritis, particularly when it occurs in senile patients, is troublesome and unfortunately is not readily relieved Often improvement of the general health of the patient by appropriate dietary regimens ameliorates the complaint. The *localized dental neuritis* that follows procaine block injections is due to the excessive amount of procaine injected into the immediate vicinity of the nerve The symptoms of paresthesia usually disappear. Postherpetic *ophthalmic neuralgia* is persistent, and its course is not affected by operative procedures Snake venom may help.

The neuralgias are common causes of pain in the face In *glossopharyngeal neuralgia* the pains are projected along the distribution of the ninth cranial nerve. The trigger zone is situated in the tonsillar fossa, and the darting pains are projected toward the ear, usually terminating in the tympanum. The pains are precipitated by yawning, swallowing and talking, but not by rubbing the face The pains resemble those of trigeminal neuralgia in their occurrence, duration, repetition and character, but they differ from those of trigeminal neuralgia in their distribution In glossopharyngeal neuralgia it will be observed that cocainization of the pharynx will result

The infection as it occurs in children is not a serious one There are moderate fever and mild congestion of the nose and throat which precede the swelling of the parotid glands. The pain in mumps is produced by increased glandular activity. This fact accounts for the time-honored procedure of a test for mumps, favored by grandmothers for many generations, of having a child who is suspected of having mumps bite a pickle. After the age of puberty mumps is a more serious disease, especially in boys and men, because of the frequent and painful complication of orchitis which may lead to testicular atrophy and to sterility. Oophoritis is less serious because the inflamed and edematous ovaries are not confined by a thick fibrous tunica like the testicles in adolescent boys or in men. There may be a minimal involvement of the parotid glands, the first symptoms being those of orchitis, which in mumps may be either unilateral or bilateral. The orchitis often is accompanied with acute severe pain, and there may be a high fever. In women a mild mastitis may occur.

EXAMINATION. There may be either a unilateral or a bilateral enlargement of the parotid or submaxillary glands or none discernible on examination Swelling of a gland usually reaches a maximum within 48 hours after onset and most often persists for 7 to 10 days. Occasionally, some enlargement of the glands of salivation can be discerned after the lapse of several weeks

In the earlier stages a restricted area of redness may be observed immediately about the orifices of the ducts of Stensen and Wharton Fever of moderate degree may be present 12 to 24 hours before swelling is observed, and it usually persists from 1 to 3 days. In many cases fever is absent.

The most important findings on examination in mumps are those indicating involvement of the epididymis and testicle This may be bilateral or unilateral, and when bilateral, sterility often ensues. There are exquisite tenderness, pain and swelling of the testicles. If the testes are involved on subsidence of the swelling, atrophy may be observed either unilaterally or bilaterally. On the basis of studies on changes in the blood diastase and amylase, some degree of pancreatic involvement is often revealed Physical findings may reveal evidence of encephalitis during the course of mumps (see Diseases of the Brain, Chapter 15).

The total leukocyte count may be moderately elevated or depressed but is usually within normal limits The differential count may reveal an absolute or a relative increase in lymphocytes from the first to the fourteenth day of the illness In contrast to the blood, the leukocyte count of the cerebrospinal fluid is of great significance in the diagnosis of the general syndrome of aseptic lymphocytic meningo-encephalitis, of which mumps virus is one of the known etiologic agents In mumps encephalitis the number of white cells of the fluid is increased The total count may range from normal to more than 2,000 per cubic millimeter. In a majority of cases the proportion of lymphocytes is from 90 to 100 per cent It is known, however, that in apparently uncomplicated encephalitis a moderate or marked increase in lymphocytes may occur in the spinal fluid A specific complement-fixing antibody may be present in the blood of adults and children who deny having had mumps

DIAGNOSIS Often the parents or the grandmother has diagnosed mumps correctly before the physician is consulted, if he is consulted at all The diagnosis in sporadic cases is difficult, for it is necessary to differentiate mumps from suppurative parotitis, enlargements due to foreign bodies in the salivary ducts, neoplasms, Mikulicz's disease and uveoparotid fever. The possible complications are numerous, and appropriate diagnostic examinations and procedures will depend on the existing complication

It is now possible to obtain serologic evidence of any type of infection caused by mumps virus. This can be accomplished by demonstrating the appearance of or increase in an antibody capable of fixing complement in the presence of mumps

antigen, and by the demonstration of the appearance or increase of a specific factor, antihemagglutinin, in the blood serum which inhibits the agglutination of chicken or human erythrocytes by mumps antigen. The first procedure is recommended

As with many serologic tests, a definite diagnosis can be made only as the disease progresses and there is a significant rise in antibody titer, revealed by successive examinations of the blood following the onset of the disease.

Chronic Inflammation. Chronic inflammation of the parotid gland may remain symptomless When symptoms do occur there is a sudden swelling and pain of the gland which commences during a meal. The swelling and pain subsides in 3 to 4 hours.

On examination during the attack the gland is greatly enlarged and tender and no secretion is discharged from the duct. Between attacks the secretion is thick and glairy Subsequent attacks may occur, frequently they do not The glands may be enlarged

Tumors. *Mixed Tumors.* Mixed tumors of the parotid gland are hard, usually ovoid and lobulated, and are situated in front of the ear and below it Tumors of this type invariably develop in the lower half of the gland, whereas adenomas and primary malignant growths of the parotid gland usually originate in the upper half of the gland. In their early stages mixed tumors are situated within the gland substance and consequently are not freely movable. The adenomas are freely movable until they become malignant.

Mixed tumors of the parotid gland develop in a congenital anomaly and seldom are discovered before early adult life. Usually such a tumor is not seen by the physician until years have elapsed and the patient has known of its presence for a long time As the tumor enlarges, it causes a rounded induration in the parotid region Situated as it is within the substance of the gland, the tumor in the course of growth sometimes causes a stretch on the facial nerve, so that partial paralysis of the nerve takes place Complete facial paralysis as the result of a parotid tumor is unusual, however, even if malignant changes have occurred within the tumor If the mass attains a large size, the skin over it may become ulcerated The ulceration causes very little pain A mixed tumor of the parotid gland grows slowly; its size is not an indication of whether or not it is malignant, and palpation will not determine this point. A search for affected lymph nodes in the region, therefore, is important.

Mixed tumors that lie superficially to the parotid gland tend to form pendant growths; in other words, tumors thus situated grow away from the gland rather than within it.

Adenomas and Cysts. Adenomas are fairly common in the parotid gland, where they begin as simple, encapsulated nodules of gland tissue As stated, they tend to occur in the middle and upper parts of the gland, seldom in the lower pole These cystic, glandlike tumors become malignant much more frequently than do the mixed tumors of the parotid gland Prior to the malignant change they grow slowly.

Carcinoma. Carcinoma of the parotid gland often begins within the normal gland tissue or in adenomas If a simple parotid adenoma has been incompletely removed surgically, the remaining adenomatous tissue seems to be a favored site for malignant disease, and a carcinoma occurring in such tissue has a bad prognosis. Carcinomas in adenomatous rests, or within the gland substance, become extensive regions of infiltration, involving much of the gland and the tissues beyond it. Carcinomatous tumors of the parotid gland are hard irregular masses but they cannot be diagnosed by palpation. They are diagnosed by histologic study of biopsy material The prognosis in malignant disease of the parotid is always serious.

THE LIPS

Thick lips or thin lips are often a racial characteristic, as in the Negro (thick) or the American Indian (thin) (see Races, Chapter 16). Tradition has it that full

lips in white races mark a phlegmatic temperament. The lips are thickened and coarse in myxedema and cretinism

The color of the lips is often significant of anemia and other conditions in which the skin is pallid, and the first evidence of cyanosis is often seen in them, their slight blueness attracting attention to the existence of cardiac or pulmonary disease.

Open, and particularly *dry and cyanosed, lips* are likely to indicate dyspnea. Open lips may be due to disease within the mouth: stomatitis, glossitis, cancrum oris, phlegmonous tonsillitis, or some form of nasal stenosis. Loose and pendulous lips in a very ill patient are suggestive of a central nervous system disorder, that is, early hemiplegia or bulbar palsy. The open mouth is seen in some normal persons, in all conditions of great prostration, and in idiots and some insane persons.

Trembling or twitching of the lips may be a symptom of general nerve fatigue, paralysis or chronic bulbar palsy. Convulsive raising of the upper lip, with an accompanying squinting of the eyes and wrinkling of the forehead, is occasionally evidence of great pain.

The term *macrocheilia* implies thickened lips. The condition is observed in children, and usually the increase in size of the lips is due to an increase in the muscle and connective tissue. In this condition the lips seem to be less prone than the tongue gradually to increase in size. When the lips have attained two or three times their normal size, the growth ceases and the size remains stationary. The increase in size may be so little in evidence that the disorder is neglected until the child reaches a self-conscious age. This great increase in the size of the lips, occasionally accompanied by increased size of the tongue and the cheek, is very much like the increases in size seen in hemihypertrophy which may involve a whole side of the body.

Unilateral deviation of the lips, the angle of the mouth being drawn to one side and downward, if not due to loss of teeth on the opposite side or to the contraction of scars, is indicative of facial paralysis, either existing alone or as a part of a hemiplegia.

A brawny, hot *swelling of the lip* may be a small abscess or a more extensive and serious carbuncular inflammation The lips are swollen as a part of the disease in the fortunately rare cancrum oris Swelling may be due to the taking of corrosive poisons, in which case the interior of the mouth will also be swollen and reddened. Bites of insects may explain a swelled lip, and among other causes are alveolar abscess, bitten lip in epileptic or other convulsive disorder, and angioneurotic edema

Foam on the lips is a common symptom during an epileptic seizure, and sometimes in the later stages of cerebral apoplexy and in pulmonary edema. It should be borne in mind that a bit of soap in the mouth is employed by malingerers in simulating epileptic convulsions

Malformations. The zone indicating the meeting of the median nasal processes during development is normally evident by double ridges and a shallow groove passing downward from the nasal septum to the margin of the upper lip; the *philtrum.*

A median defect of the upper lip or jaw, through incomplete union of the median nasal processes, is a rare anomaly An equally rare anomaly is imperfect fusion at the midplane between the mandibular processes which form the lower lips and jaw A slanting cleft may extend from the mouth up the cheek. It is due to the failure of union between a maxillary process and the nasal processes.

Cleft Lip or Harelip. This is a common disfiguring congenital deformity of the face. It is so named because of its resemblance to the lip of a hare. It is frequently associated with a cleft of the soft palate or the hard palate or both. The deformity is the result of a failure of union of the embryologic components that after union differentiate the nasal and buccal cavities The first or mandibular arch very early in embryonic life becomes separated into a short upper maxillary process and a

longer, lower mandibular process. The maxillary process together with that of the other side and the intervening portion known as the premaxillary (frontonasal) process, which has descended in the median line from the head, unite and form the superior and lateral boundaries of the oral cavity and the nose If the premaxillary process unites with only one maxillary process, a unilateral cleft is found, but if it unites with neither, a bilateral cleft is present, the premaxillary process extends forward as a proboscis, and a cleft exists in the alveolar ridge. It can thus be seen that all gradations of a deformity may exist from a slight V in the lip to a complete cleft of lip, alveolar ridge and palate. The main symptom of harelip and cleft palate is nasal voice On examination the degree of disfigurement is proportionate to the degree of the congenital deformity. The diagnosis is obvious.

Inflammations. Inflammations of either the upper lip or the lower lip may be the result of any ordinary pyogenic infection which has entered the lip through an abrasion The *staphylococcus* is a common offender in these inflammations.

Inflammation of the lower lip is not nearly so important clinically as inflammation of the upper lip, since a localized furuncle or a diffuse inflammation of the upper lip may extend and produce a sinus thrombosis with subsequent death of the patient Any inflammation of the upper lip of any magnitude at all should be considered as serious These lesions are much more serious in their import than are the malignant tumors of the lip, which have received much more attention from members of the medical profession

Herpes (Virus Infections) The herpes virus infections of man occur in a variety of clinical types. Herpes simplex groups of viruses may cause (1) diseases of the skin, (2) diseases of mucous membranes, (3) diseases of the eyes, (4) diseases of the nervous system and (5) herpes progenitalis.

One of the commonest lesions of the lip is *herpes febrilis*. The etiology of herpes febrilis, the common herpetic vesicles or coldsores or fever blisters, is a filtrable virus that can be demonstrated by inoculating the corneas of rabbits The virus of herpes febrilis (herpes simplex) has been thought to be identical with that causing encephalitis lethargica, and consequently it has been studied intensively

The patient who has a recurrent attack of fever blisters is as a rule singularly free from severe systemic symptoms It seems that such persons have become carriers of the virus and are likely, after nonspecific stimuli, such as fever, menstruation or emotional upsets, to have recurrent manifestations of herpetic infection.

The lesion of herpes simplex is heralded by a feeling of irritation or burning pain in the area of skin involved Erythema quickly followed by papulation and vesiculation ensues in this area The vesicles are grouped, thin-walled lesions which rupture soon, in from a few hours to a day The lesions may occur anywhere on the skin, but definitely tend to appear most commonly at mucocutaneous junctions, on the lips and on buccal surfaces of the mouth, and to recur in the same sites The lesions heal without scar formation

Fissures. Fissures of the lip sometimes follow trauma Less often, a fissure remains after the healing of herpes labialis. Generally fissures of the lip result after prolonged drying of the mucosa as a consequence of being out-of-doors in the heat and sun and dust most of the time, or inside where there is considerable drying of the lips from exposure to high temperatures and low humidity. Fissures may remain as such, or they may become ulcerated

On examination of a chronic fissure it is seen that the fissure has formed and has healed again and again, without there being any manifestation of malignancy. However, although a fissure may remain for years without notable change, malignant degeneration may begin at any time along its borders Unless a fissure is picked with the finger nails, it usually does not bleed. When a fissure begins to bleed rather easily it is time to consider that a cancer may be arising in the cleft.

Fissure of the lip may become painful, the patient complaining of the pain, for example after taking a chew of tobacco or a dip of snuff, when the tobacco-laden saliva gets into the fissure.

Perlèche. Perlèche, as the term is now employed, usually denotes the changes at the angles of the mouth which occur in vitamin B complex deficiency. However, idiopathic perlèche and pseudoperlèche do occur.

Idiopathic perlèche includes instances of perlèche encountered devoid of concomitant clinical or laboratory findings, which, in the light of present knowledge, must simply be considered as of idiopathic origin. In some instances there is an accompanying salivary drooling, or possibly excessive or chemically altered salivary secretion in association with scrotal tongue, with geographic tongue or with macroglossia.

Pseudoperlèche includes those instances of contact dermatitis, neurodermatitis, seborrheic dermatitis, atopic dermatitis, severe chapping and herpes which occur in the region of the oral commissures, and because of the movement in this area by mastication and talking perlèche-like fissuring ensues. Perlèche-like involvement is also seen at times in the rhagades of congenital syphilis and as an extension to this area from mucous patches of syphilis in the mouth Transitorily, perlèche-like involvement may result from the trauma of manipulations incidental to dental therapy.

The symptoms of perlèche are mild, usually consisting merely of a feeling of dryness and at times a slight burning sensation. Deep, infected fissures may be painful and, though rarely encountered, occur chiefly in perlèche of adults.

Objectively, the epithelium of one or both labial commissures is somewhat macerated, either adherent or easily detached, and wrinkled. Later the wrinkles become deeper, often forming one or more transverse fissures with little if any tendency to bleed. The involvement usually stops rather abruptly just within the mucocutaneous junction of the commissure, but extends as a localized erythematous scaling dermatitis, usually with fissuring, from a few millimeters to as much as 2 cm or more outward and downward from the mouth angle onto the skin of the lower lip Untreated, the lesions in all types of perlèche have a tendency toward spontaneous remission and exacerbation, but they rarely disappear completely.

Pyogenic Ulcers. Pyogenic ulcers of the lips are a not uncommon end result of various traumas to the lips. Some of these ulcers result from direct trauma, such as a blow to the lip from a fist or being thrown against the windshield in an automobile accident On examination the elevated surface is soft to touch and the whole lesion is soft when it is grasped between the fingers. If the lesion is of long duration, it may be hard on palpation Very little bleeding occurs from manipulation and handling of these lesions, and the adjacent tissues are but slightly hyperemic.

Some of these ulcers may be tuberculous in origin Tuberculosis of the lip occurs on the vermilion border without a like lesion elsewhere in the mouth. Biopsy may be required for diagnosis

Benign Ulcers. Benign ulcers occur either on the upper lip or on the lower lip. On examination these spontaneous ulcers usually are manifested only by a defect in the epithelium Such lesions may continue for months, even years, without noticeable change, or they may heal, only to recur Recurrent lesions may end in malignant disease Ulcers of this type sometimes occur on the lower lip, but not usually [illegible]

[illegible]

[illegible] frequently are on the upper lip. Malignant lesions, on the con-

trary, commonly occur on the lower lip. Chancres develop and may attain considerable size within a few weeks Carcinomas of the lip do not progress so rapidly.

On examination a chancre of the lip, if it has been present for some time, has an indurated feeling to the examining finger, and it is elevated and may be sharply circumscribed. If a chancre is examined in its early stages, it is a small nonelevated lesion with but little induration about its edges.

Positive serologic reactions of the blood or the spinal fluid, conjoined with an ulcer of the lip in a young person, may be presumptive evidence that the ulcer is a chancre Positive serologic reactions, with an ulcer on the lower lip in an older person, may not be of diagnostic significance.

Lesions which are the result of undernutrition may appear on the lip as punched-out ulcers, and it is likely that similar lesions will be found on the tongue or elsewhere in the mouth

Wounds. Wounds of the lips when properly approximated heal readily because of the free blood supply. This free blood supply also accounts for the extensive swelling which occurs after injury or infection, the latter, however, only rarely occurring after injury

Tumors. The commonest tumors of the lips are the benign cysts that form in the glands of the mucosa These are small bluish tumors occurring near the vermilion border, more frequently of the lower lip On examination the dome of the benign cyst is firm and uniform in outline, and it may or may not be translucent.

Lymphangiomas. Some of these lesions are congenital in origin but may not be manifested during the first several years of life. They may occupy a part or all of the lip Although soft to touch, they are not reduced in size by pressure. If a lymphangioma results from trauma, as is often the case in middle-aged persons, there is a firm region which is due to the scar which resulted from the trauma. There is little difficulty encountered in the diagnosis of the lymphangiomas of congenital origin, for they are uniformly boggy and compressible to the touch without being reducible in size Some lymphangiomas of the lip attain enormous size and are grossly disfiguring.

Angiomas. In infants the blood vessels, mainly the veins, of the lips sometimes become enlarged, forming a large protrusion. The initial enlargement may be noticed at birth or soon after birth as a dusky blue, slightly swollen spot on the lip. As the child grows, the swelling enlarges, sometimes rapidly.

Hemangiomas. These lesions are of congenital origin and are always reddish or purple. On palpation they are soft and compressible and are reduced in size or obliterated by pressure. In children they may be increased in size when the patient cries or coughs, also in adults who have extremely large hemangiomas on the lips, coughing increases the size of the tumors.

Cutaneous Horns. Cutaneous horns of the lips are labial lesions common in advancing years; they may occur, however, in young adult persons Cutaneous horns of the lips do not differ from cutaneous horns on any other part of the body except that on the lips they are more likely to become malignant than elsewhere. Over the rest of the body the horns may occur in successive generations and be shed

The first appearance of a cutaneous horn is a small elevation hard to the touch with a sharply defined base. Occasionally a cutaneous horn will develop on the base of an ulcer or in a fissure or a granuloma These horns vary considerably in consistency, one part may be very hard and cornified, and another part may be granulomatous Some of the very small horns may be moderately hard. They grow in length rather than in diameter, consequently their name When inflammation exists around the base of these tumors, it should excite suspicion that the tumor is malignant. It is remarkable how long a patient will put up with one of these long excrescences on the lip. In generalized cutaneous horns there is no known treatment Roentgen therapy is not effective.

Pigmented Moles. Occasionally along the mucocutaneous border of either the upper lip or the lower lip there will be a darkly pigmented mole. Under no circumstances should a specimen of such a lesion be taken for biopsy. These moles are potentially malignant. Some of them are highly malignant (melano-epitheliomas).

Cancer. Cancer or epithelioma of the lip almost always affects the lower lip rather than the upper lip. It is commonly *secondary to a chronic fissure, leukoplakia* or *keratosis* of the lip, and it is a disease usually of middle-aged farmers who are exposed to sun, wind and drying of the lips These lesions are hard, indurated, ulcerating or bleeding, and often produce considerable stiffening of the surrounding tissues.

The disease extends through the lymphatic channels, which pass down and out from the lips to the submaxillary lymph nodes and then to the nodes along the great vessels of the neck. It is in these regions that the lymph nodes are affected by the spread of cancer from the lip. The middle of the lower lip drains into a node in the submental region in front of the submaxillary nodes Finding this node enlarged is not of much significance, for it frequently is enlarged when there is no demonstrable lesion of the lip Enlarged nodes may be found on both sides of the neck and are secondary to cancer of the lip.

A *primary cancer of the lip* is defined as one developing without a previously existing fissure or ulcer. It occurs more frequently in men than in women, and about 10 times as frequently on the lower as on the upper lip. Cancer of the lower lip is almost invariably of squamous cell type. On the upper lip it frequently represents invasion of the lip by a carcinoma of the skin, and may be either squamous cell or basal cell carcinoma.

Primary cancer of the lip is a localized, hard, deep-seated lesion of firm density, and is unyielding on pressure Examination of the epithelium over the lesion reveals that the surface is being approached or that there already is ulceration. When ulceration of these lesions occurs, there is free bleeding on the slightest trauma; palpation of these hard ulcers causes them to bleed A patient may be unaware of the seriousness of an ulcer on the lip until the ulcer begins to pain or to become deeply ulcerated, or the lymph nodes under the jaw become ulcerated

Liljencrantz classifies cancer of the lip by stages in its development determined on examination· clinical stage I: lesion less than 1 cm. in diameter without muscle infiltration; stage II moderate-sized lesion (1 to 3 cm. in diameter), usually accompanied by early muscle infiltration, stage III large lesion (more than 3 cm in diameter) with deep infiltration, and all lesions with involvement of bone or cervical lymph nodes

Cervical lymph nodes may contain cancer cells and not be enlarged Ulcerated, infected primary lesions often cause inflammatory hyperplasia, and it is frequently impossible to distinguish clinically between inflammatory and metastatic cervical nodes

Biopsy establishes the diagnosis Any ulcer, fissure, scaling, heaped-up or papillomatous lesion remaining on the lip for more than one month should be suspected of potential malignancy. Inspection and gentle palpation are most important in making a clinical diagnosis A negative blood serologic reaction and absence of history rule out coexistent syphilis A positive serologic reaction does not exclude cancer and should not be the cause for delaying biopsy

THE MOUTH

Surface Anatomy. In looking into the mouth one sees the tongue below and the roof above, surrounded in front and on the sides by the teeth On each side are the inner surfaces of the cheeks and posteriorly are seen the uvula, the arches of the palate and the pharynx On the mucous membrane of each cheek, opposite the second upper molar tooth, is a small papilla through the top of which opens the duct of the parotid gland A small probe can be inserted into the duct from the oral cavity and passed outward and backward toward the gland.

Size of the Mouth. The primitive slit may fail to reduce normally (macrostomia); on the contrary, the degree of closure may be excessive (microstomia). Size of the mouth also seems to be hereditary.

The Buccal Cavity. Odor of the Breath (*Halitosis*) There are many variations from the normal in the odor of the breath. Local conditions in the mouth may be accountable for an unpleasant or foul odor of the breath. In dehydration, when sordes have collected on the teeth, the breath is likely to be stale and musty. A foul odor attends in some degree all forms of stomatitis and glossitis, and is most fetid in the mercurial and gangrenous forms. Caries of the teeth, necrosis of the jaw, pharyngeal or tonsillar diphtheria, follicular tonsillitis and lacunar concretions are local conditions that may explain the existence of unpleasant emanations. Frequently a bad breath attends migraine headaches and chronic alcoholism A hot feverish breath is common in febrile disorders An ammoniacal, urinous odor is not uncommon in the severer grades of uremia. A heavy, sweetish odor is perceived in bad cases of diabetes mellitus, often preceding or accompanying diabetic coma

It is well to recall, however, that the normal human breath is odorless and that many instances of halitosis are the so-called essential halitosis. It has been said that man's breath becomes infected by the bad quality of food, by the bad state of the teeth and still more by old age At one time or another during life everyone suffers from malodors coming from the mouth. The presence of offensive breath does not cause pain or other subjective inconvenience If the patient is aware of halitosis, it may be the cause of deep despondency which arises because in most instances the foul odor is not at all recognized, or at most only partially so, by the patient

There is a popular opinion abroad that bad breath originates most frequently from disorders of the stomach and colon—constipation. Gas cannot pass from the stomach or from the intestine back through the collapsed esophagus under normal conditions except in belching In certain diseases of the esophagus in which there is retention of food in a dilated portion or in a diverticulum, there may be foul odors on the breath Pyloric stenosis and the late stages of cancerous ulceration of the stomach are productive of pronounced foul odors. In cases of fecal vomiting and gastrocolic fistulas a fecal odor of the expired air may be observed

Dryness of the Mouth. Dry mouth due to diminished secretion of saliva may lead to redness, soreness and fissuring of the mucous membranes, and if long-continued, eventually to atrophy In severe instances rapid deterioration of the teeth follows Chewing and swallowing may become difficult Inadequate amounts of saliva, according to Allington, may result from (1) a decrease in salivary gland substance (congenital hypoplasia, senile atrophy, destruction following surgical intervention, irradiation, inflammation or neoplastic infiltration), (2) disturbances of innervation (central or peripheral nerve lesions, emotional states, psychoses, interference with conduction of nerve impulses due to drugs, toxic agents or metabolic disturbances); (3) dehydration and (4) unknown causes (Sjogren's syndrome). In *Sjogren's syndrome* dry mouth is associated with dryness of the eyes and of the mucous membranes of the nose, throat and vagina and with deficient gastric secretion. Many of these features suggest deficiencies of vitamin A, nicotinic acid and riboflavin, and some of them are seen in pernicious anemia, iron deficiency anemia and *Plummer-Vinson syndrome*. There is a frequent association of the syndrome with rheumatoid arthritis and with the endocrine changes that occur in postmenopausal women. In aging men after many years of excessive smoking, chewing of tobacco or dipping snuff, dry mouth is common. Treatment of dry mouth must be directed toward the causative factor.

Salivary Taste Hormones. Dryness of the mouth from any cause often impairs taste Reasons for this clinical observation are partially accounted for by dryness of the mouth in some, and in others by the hereditary absence of salivary taste hormones It seems that most persons can taste saccharin and sodium chlor e on a

wet tongue, but some cannot taste these substances on a dry tongue. Cohen and Ogdon have demonstrated a salivary taste hormone which could account for these discrepancies of taste on dry tongues and in some a normal absence of this hormone.

The Sense of Taste. The four primary taste sensations are bitter, sweet, acid and salt.

Taste buds, the end-organs of the gustatory sense, cannot be identified grossly. They are scattered over the mucous membrane of the mouth and tongue at irregular intervals, and occur especially in the sides of the vallate papillae. They decrease in number gradually during adult life and rapidly in extremely old age.

The taste fibrils run in both the glossopharyngeal nerve and the trigeminus nerve, the former supplying the posterior third of the tongue, the latter the anterior two thirds. A complete loss of taste may result from trigeminal disease alone, and occasionally from lesions affecting only the glossopharyngeal nerve. It seems, therefore, that the gustatory fibers may at times be present solely in the trigeminus and at other times solely in the glossopharyngeal nerve Some of the taste fibers may pass by way of the chorda tympani, since a partial loss of taste may be present in facial paralysis. Ordinarily, a solution of sugar is sufficient to enable one to detect any impairment of taste.

The disorders of the gustatory sense are ageusia (loss or impairment of the sense of taste) and parageusia (perversion of the sense of taste)

AGEUSIA. Impairment or absence of the sense of taste may be due to local unhealthful conditions of the mucous membrane of the tongue. If the tongue is dry, taste is much lessened or abolished. Since the sense of smell plays a considerable part in the production of the sensations ordinarily referred to the sense of taste, a patient who has acute coryza or bad colds may complain of a loss of taste Large doses of the bromides blunt the sense of taste.

The lesions affecting the sense of taste may be basal meningitis, tumors and injuries. Ageusia may be one of the manifold symptoms of hysteria, which, with facial paralysis, is the commonest cause of a partial loss of the sense of taste. In each case associated symptoms must determine the diagnosis.

PARAGEUSIA Purely subjective perversions of the sense of taste are usually indicative of hysteria, they may constitute the aura of epilepsy; in the insane they may be hallucinations. Various bad tastes frequently are a source of complaint of neurotic patients. The administration of certain drugs may give rise to disturbed taste sensations.

Petechiae. Small extravasations are occasionally seen on the buccal mucous membrane, and when present, may be caused by one of the grave anemias, hemophilia, purpura hemorrhagica or scurvy; or they may be the hemorrhagic infarcts of ulcerative or septic endocarditis.

Exanthems, Erythema and Vesicles. The rash of measles is often seen on the pharyngeal and palatal surfaces prior to its appearance on the skin, and Koplik described, as absolutely characteristic of measles, small red spots with minute blue-white centers on the inner surface of the cheeks which disappear as the rash develops. The angry redness of scarlet fever, involving the entire oral and faucial surfaces, is very striking A slighter redness is present in simple erythematous stomatitis, and the rare occurrence of a salivary calculus with accompanying redness should be remembered Vesicles when present may be the beginning of an aphthous stomatitis, herpes, the eruption of varicella or smallpox, pemphigus or recent burns.

Pigmented Spots, Ulcers and Sloughs. Dark spots, usually of various shades of brown, occur in dark-skinned races or in mixtures of white and black races All of those diseases such as Addison's disease which cause a darkening of skin color may be manifested by dark spots in the mouth

Small grayish ulcers with reddened margins, which have begun as vesicles situated on the inside of the lips and cheeks and on the edges of the tongue, are the lesions of aphthous stomatitis, the common canker sores. If removal of exudate on the gums, buccal surfaces, tonsils or soft palate reveals ulcerations, the exudate may

be due to Vincent's angina. White, curdlike patches, beginning on the tongue ar
spreading to the inside of the lips and cheeks and leaving, if detached, a normal
slightly ulcerated surface, form the disease known as thrush Aphthous lesions
the mouth, recurrent ulceration of the genitals accompanied by iridocyclitis fo
lowed by hypopyon constitutes Beçhet's syndrome. The etiology is unknown.

Salivation and Dribbling. The amount of saliva which is secreted in 24 hou
is, under normal circumstances, from 1,000 to 1,500 ml Ptyalism or hypersecretio
of saliva, in which this amount is greatly exceeded, may occur in early pregnanc
dementia praecox, encephalitis, rabies and sometimes attends the menstrual perio
The pain due to dental causes, alveolar abscess, or trigeminal neuralgia, and th
process of dentition itself, will induce an excessive formation of saliva Dribbling c
saliva may occur as a result of hunger and, at times, because of inability to retai
saliva, as during sleep

Stomatitis. Stomatitis often accompanies infectious diseases such as scarlatina measles, influenza, typhoid and rickettsial fevers and botulism The blood dyscrasia and certain forms of avitaminosis may cause pathologic changes in the mouth During the eruption of the temporary or milk teeth there may be stomatitis. From the standpoint of general medicine, catarrhal gingivitis, catarrhal stomatitis and so-called aphthous stomatitis should be looked on as a complication of many and various disease conditions that are manifested in the mouth

Epidemic Stomatitis (So-Called Foot and Mouth Disease). Epidemic stomatitis is a disease of cattle and goats that is highly communicable to man. It is characterized by [illegible] in temperature and by eruption of vesicles on the mucous membranes of th[illegible] filtrable virus which is present in the fluid contents o[illegible] kidneys, the salivary glands and the mammary glands [illegible] the mouth Occasionally the virus may produce the disease by entry [illegible] The period of incubation lasts from 3 to 10 days

In the early stages of the infection there may be slight fever, chills, headache, muscular pains and general malaise These symptoms are followed by the characteristic manifestations, which are swollen, painful lips and a thick, coated tongue showing imprints of the teeth Within 2 or 3 days yellow vesicles appear over the soft tissues of the mouth, rarely on the hard palate There is profuse salivation In severe infections, 2 or 3 weeks after the onset of the disease, large vesicles may develop on the hands and sometimes between the toes. The vesicles may increase in size and coalesce to form blebs Occasionally the vesicles are observed on the lower part of the nose and may extend to involve the eyelids

Acute Herpetic Gingivostomatitis. Acute infectious gingivostomatitis, aphthous stomatitis, catarrhal stomatitis, ulcerative stomatitis, Vincent's stomatitis are the cognomens of this disease

This is a common disease of young children due to the virus of herpes simplex There are fever, irritability, red swollen gums, a vesicular eruption on the mucous membranes of the mouth, oral fetor, and local lymphadenopathy A constitutional reaction is always present but varies in severity; a high fever, temperature from 104 to 105 F (40 to 40.5 C) is common

The commonest finding is a characteristic involvement of the gums which varies from a thin red line along the dental margin to extreme redness and swelling of the gums In the rare infant, infected before the eruption of teeth, the gums escape involvement. Lesions in the rest of the mouth, when seen very early, consist of a few to many small vesicles, which soon rupture, leaving grayish lesions of varying size, single or confluent, that may become ulcers. The tongue and cheeks are most commonly involved

In some patients the tonsillar region is affected early, and the disease resembles acute tonsillitis of bacterial origin Submaxillary lymphadenopathy of varying degree

is extremely common. The disease lasts from 10 to 16 days regardless of therapy. Pain tends to disappear within about 1 week from onset, or about 3 or 4 days before the lesions heal. Scarring is absent or very slight. Swelling of the gums and lymphadenopathy, among the first signs to appear, usually persist for many days after the ulcers heal.

Recurrent Stomatitis. Occasionally herpetic stomatitis recurs. The local lesions are similar to those described in the foregoing paragraphs, but there is a virtual absence of systemic reaction in patients so affected. Virus can be isolated from the lesions, and circulating antibodies are present at the onset of symptoms. The distinction of such lesions from etiologically different but clinically similar types of recurrent stomatitis depends on isolation of the virus or on results of biopsy, or both.

Gangrenous Gingivitis or Noma. Gangrenous gingivitis or noma is an acute progressive gangrenous process of unknown origin primarily occurring in children, usually beginning about the buccal gingivae and spreading rapidly to the mucous membranes of the cheek. Soon there is extensive sloughing of the adjacent soft tissues about the mouth. The intense rapidity of the progress of the disease, the absence of a line of demarcation within the inflamed area, and the comparative freedom from pain are characteristics of noma The disease is attended with great exhaustion and almost invariably is fatal.

Oral Diseases Due to Physical and Chemical Agents. The oral cavity is frequently exposed to injurious agents The ingestion and inhalation of foreign substances into the oral cavity lead to an accumulation of chemical, physical and bacterial irritants which are prone to settle along the gingival crevices about the teeth. The gingival portion of the oral mucosa is in a constant state of low-grade inflammation if not actual disease.

The different types of structure, ranging from the oral mucosa to the highly specialized and mineralized enamel, account for the great variety of response that is displayed in the oral cavity from the influence of physical and chemical agents. However, there are other channels of entry of noxious agents into the body (see Diseases Due to Physical and Chemical Agents, Chapter 19).

Schour and Sarnat record that localized abrasions of the enamel of the teeth are found in occupations in which workers hold various objects between the teeth while at work, such as tacks, nails, pipes, musical instruments and whistles. Fractures of the enamel and traumatic effects on the periodontal structures also occur. Dust of abrasives such as sand and cement or ordinary powders and pastes used to clean the teeth may cause abrasions. A distinction is made between abrasion and attrition. Attrition is the physiologic wear of teeth incident to age.

Acid fumes deposited on the exposed portions of the teeth react with the enamel, and decalcification results. Similar action on the teeth results from protracted vomiting in which the hydrochloric acid from the stomach decalcifies the enamel. The ingestion of acid carbonated drinks accomplishes more slowly the same end results of decalcification and often caries

A high incidence of tooth decay and caries has been reported among workers who are exposed to sugar dust. The sugar dust is supposed to be deposited along the labial gingival surfaces of the crown where it stagnates and induces abnormal fermentation, and with the aid of bacteria induces acid production and decay of the teeth

Green staining of enamel, pigmentation, has been observed among copper workers Among silver workers there may be a black staining and there are black

bacteria

The exogenous gingival pigmentation of occupational origin is distinguished from

the endogenous brown melanin of the gingivae that is seen normally in the Negro and the mulatto, and in white persons who have Addison's disease. This melanin is situated in the basal layer of the epithelium, whereas coal dust and metal dust accumulate on the surface and penetrate to various depths of the epithelium and sometimes even the dermis. The sulfides of heavy metals are found only in the dermis but become visible as lines about the gingivae. Certain common heavy metals produce the pigmentation of the gingivae that usually, but not always, follows the ingestion or inhalation of the metal That the ingestion, inhalation, or injection of lead or other heavy metal is not sufficient to produce a line is well illustrated in lead poisoning which follows the injection of lead for the treatment of metastatic malignant disease The essential factor is the presence of chronic gingivitis. Lead absorption does not cause inflammation, but rather inflammation brings out the lead line. The lead line is manifested as faint mottled patches of black at the edge of the gum; a fine black line along the entire gum margin or a black line, wider along the margin of the gums. Patches of black or blue-black pigment occur on the cheeks The gingival lines produced by the heavy metals, lead, mercury and bismuth cannot be differentiated one from the other.

Once a poison such as lead and mercury enters the blood stream, it is precipitated as the heavy sulfide in the colon and at gingival margins or into the oral tissues.

The alveolar processes and jaws may be the first structures affected by blood-borne agents. This is exemplified in yellow phosphorus poisoning in which the "phossy jaw" is a characteristic finding, in mercurial poisoning in which the teeth become loose and are eventually exfoliated, and in radium poisoning, which was first diagnosed because of toxic effects on the jaw bones.

In the early stages only the alveolar bone is affected. In mercury poisoning the disease process may be limited to the alveolar portion of the mandible and maxilla and rarely extends much beyond the level of the apexes of the teeth. In the later stages, however, the osteomyelitis may include a greater portion of the jaws and is followed by sequestration.

Lesions of the Mouth in Vitamin Deficiency. Lesions of the lips, gums, tongue and buccal mucous membranes occur as manifestations of deficiency of ascorbic acid and of some of the fractions of the vitamin B complex. These manifestations are seldom found in pure form.

Oral lesions associated with deficiency of riboflavin begin as an oral pallor, followed by maceration and superficial transverse fissuring in the angles of the mouth. These lesions are a type or types of perlèche A superficial denudation of the mucosa may occur and cause the lips to become abnormally red along the line of closure In addition to the cheilosis there are seen fine, scaly desquamations on a mildly erythematous base in the nasolabial folds, on the alae nasi, in the vestibule of the nose and on the ears. Associated with these lesions, keratitis, part of a riboflavin deficiency may be present.

Stomatitis and glossitis appear early in the course of nicotinic acid deficiency disease and they are manifested by swelling and redness of the margins and tip of the tongue. As the disease progresses, the redness becomes more intense until the parts assume a fiery scarlet hue. Ulcerations appear along the sides, the tip and the under surface of the tongue and on the buccal mucosa opposite the molar teeth. The ulcers may be covered with a thick, gray exudate.

The function of ascorbic acid is concerned with the formation and regulation of the intercellular matrix When deficiency exists, gingival lesions or scurvy, occurs. The essential lesion of scurvy is a vascular disturbance which results in swollen and boggy gums that bleed easily, and may progress to actual ulceration. Chewing is difficult and involvement of the alveolar bones causes the teeth to loosen and fall out. The teeth themselves may be affected by the scorbutic process The dentin and enamel become coarse and defective with resulting rapid and early decay of the teeth.

Hemorrhage into the buccal mucosa may result from damage to the vascular epithelium. Lesions of the gums will not occur if the teeth have been extracted.

Mucous Cysts. Mucous cysts sometimes arise from the mucous glands of the mouth and of the tongue itself. The anterior lingual gland often is affected As a rule, these mucous cysts are small and are felt as hard, rounded bodies beneath the mucous membrane. Dermoid cysts occur in connection with the tongue, but very rarely.

Leukoplakia. Leukoplakia occurs principally in men, and is said to occur more frequently in men who smoke than in nonsmokers. This statement, however, is questionable. The condition begins with hyperemia, following which a whitish granular surface develops. This white granular surface may remain stationary for years, or it may extend, or malignant disease may supervene. The beginning of a malignant process is suspected when the whitish areas begin to pile up and form wartlike structures. Without any warning, however, by changes in the white areas, metastatic nodules may appear in the neck, and after their appearance it is found that the leukoplakia has developed into a malignant condition The lesions, before malignant change develops, are soft to the touch; after malignant disease develops, there is a considerable amount of induration, and the border line, which has previously been definite, now becomes indistinct and hard.

Leukoplakia is to be distinguished from the common benign condition of the buccal surfaces of the lips and anterior pillars of the tonsils characterized by multiple small yellowish spots These spots are enlarged sebaceous glands, and the disease is known as *Fordyce's disease* Fordyce's disease is distinguishable from the Fox-Fordyce syndrome which involves the apocrine glands of the axillae and pubis The latter is under endocrine influence. Lichen planus may resemble leukoplakia

SUMMARY OF ORAL CANCER

Carcinoma occurs within the oral cavity considerably less frequently than it does on the lip. In 6 out of 10 who have intra-oral cancers the tongue is involved; 2 out of 10 will have cancer of the floor of the mouth; 1 out of 10 has the lesion on the cheek, and the last 1 will have it on the gums and the soft palate

Intra-oral carcinoma tends to be more infiltrative in regard to both muscle and bone than does cancer of the lip, and carries a correspondingly higher mortality rate. It tends to produce earlier metastasis in the deeper cervical lymph-node groups. These metastatic lesions may be either contralateral or bilateral but rarely ipsilateral.

Leukoplakia, on the lip or in the mouth, must be regarded as an important precursor of cancer A high percentage of tongue cancer is found to be associated with syphilis and leukoplakia Any ulcer, fissure, nodule or papillary growth existing for more than 2 or 3 weeks should be investigated. Thickened patches of leukoplakia are suspected of being malignant when there is any change in their size or texture Of the various inflammatory lesions which appear like ulcerating malignant lesions [illegible] sermann Biopsy

THE JAWS, TEETH AND GUMS

THE JAWS

Familial Fibrous Swelling. Various diseases of the jaws have been called fibrous dysplasia, fibrous osteoma, osteofibroma and ossifying fibroma, which are now regarded as variants of a fibrous dysplasia. Several members of a family may be affected with fibrous dysplasia of the jaws.

The disorder is characterized by massive swelling of the cheeks and jaws beginning during the first three years of life. Dentition is defective. There are no associated symptoms or systemic manifestations unless the lower jaw becomes so large that it prevents closure of the mouth and interferes with respiration and speech.

the endogenous brown melanin of the gingivae that is seen normally in the Negro and the mulatto, and in white persons who have Addison's disease. This melanin is situated in the basal layer of the epithelium, whereas coal dust and metal dust accumulate on the surface and penetrate to various depths of the epithelium and sometimes even the dermis The sulfides of heavy metals are found only in the dermis but become visible as lines about the gingivae. Certain common heavy metals produce the pigmentation of the gingivae that usually, but not always, follows the ingestion or inhalation of the metal That the ingestion, inhalation, or injection of lead or other heavy metal is not sufficient to produce a line is well illustrated in lead poisoning which follows the injection of lead for the treatment of metastatic malignant disease. The essential factor is the presence of chronic gingivitis Lead absorption does not cause inflammation, but rather inflammation brings out the lead line The lead line is manifested as faint mottled patches of black at the edge of the gum, a fine black line along the entire gum margin or a black line, wider along the margin of the gums. Patches of black or blue-black pigment occur on the cheeks. The gingival lines produced by the heavy metals, lead, mercury and bismuth cannot be differentiated one from the other

Once a poison such as lead and mercury enters the blood stream, it is precipitated as the heavy sulfide in the colon and at gingival margins or into the oral tissues.

The alveolar processes and jaws may be the first structures affected by bloodborne agents This is exemplified in yellow phosphorus poisoning in which the "phossy jaw" is a characteristic finding, in mercurial poisoning in which the teeth become loose and are eventually exfoliated, and in radium poisoning, which was first diagnosed because of toxic effects on the jaw bones.

In the early stages only the alveolar bone is affected In mercury poisoning the disease process may be limited to the alveolar portion of the mandible and maxilla and rarely extends much beyond the level of the apexes of the teeth In the later stages, however, the osteomyelitis may include a greater portion of the jaws and is followed by sequestration

Lesions of the Mouth in Vitamin Deficiency. Lesions of the lips, gums, tongue and buccal mucous membranes occur as manifestations of deficiency of ascorbic acid and of some of the fractions of the vitamin B complex These manifestations are seldom found in pure form

Oral lesions associated with deficiency of riboflavin begin as an oral pallor, followed by maceration and superficial transverse fissuring in the angles of the mouth These lesions are a type or types of perlèche. A superficial denudation of the mucosa may occur and cause the lips to become abnormally red along the line of closure In addition to the cheilosis there are seen fine, scaly desquamations on a mildly erythematous base in the nasolabial folds, on the alae nasi, in the vestibule of the nose and on the ears Associated with these lesions, keratitis, part of a riboflavin deficiency may be present.

Stomatitis and glossitis appear early in the course of nicotinic acid deficiency disease and they are manifested by swelling and redness of the margins and tip of the tongue As the disease progresses, the redness becomes more intense until the parts assume a fiery scarlet hue Ulcerations appear along the sides, the tip and the under surface of the tongue and on the buccal mucosa opposite the molar teeth. The ulcers may be covered with a thick, gray exudate

The function of ascorbic acid is concerned with the formation and regulation of the intercellular matrix When deficiency exists, gingival lesions or scurvy, occurs The essential lesion of scurvy is a vascular disturbance which results in swollen and boggy gums that bleed easily, and may progress to actual ulceration Chewing is difficult and involvement of the alveolar bones causes the teeth to loosen and fall out. The teeth themselves may be affected by the scorbutic process. The dentin and enamel become coarse and defective with resulting rapid and early decay of the teeth.

nence to the angles of the mandibles. The reflex is obtained by tapping the lower jaw with a reflex hammer as illustrated in Figure 6-71.

The temporomandibular syndrome is a temporal or bitemporal headache originating from the muscles of mastication and from the fibers of the temporomandibular joints (Williams).

Closure of the bite resulting in a dislocation of the stresses on the muscles of mastication may produce pain that is referred to the temporal region. Tearing of the anterior portion of the joint capsule resulting from extraction of molars with the patient under general anesthesia may result in pain in the region of the joint. Closure of the bite will produce a daytime headache, while injury to the joint capsule is likely to produce pain at night when the mandible drops during sleep. Closed bite rarely produces pain Capsular injury is a relatively commoner, but still an unusual, cause of pain in the head.

Spasm. Trismus or lockjaw, a tonic spasm of the masseter and temporal muscles whereby the jaws are held firmly together, may occur as a symptom of trismus neonatorum, tetanus, strychnine poisoning, hysteria, epilepsy or disease of the brain, and is sometimes a reflex from dentition.

Paralysis. In paralysis the masseter and temporal muscles do not contract and there is inability to masticate on the affected side Paralysis of these muscles may indicate hemorrhage into the pons, basal lesions (meningitis, tumor, caries) or neuritis

Pain and swelling from disease of the maxillae, mumps, quinsy or trichinosis may prevent the opening of the mouth and interfere with mastication.

Ankylosis. Ankylosis of the mandible is seen following traumatism or infection to the temporomandibular articulation. A pseudoankylosis may be due to extra-articular disease The ankylosis may be fibrous or osseous. Unilateral ankylosis, if it occurs before the fifteenth year, presents a disfiguring shortening deformity of the affected side.

Malignant Tumors. The ulcerative type of malignant lesion may not be impressive on inspection On examination the border of the ulcer is hard and irregular in outline with varying degrees of fixation Usually the tumor involves one or more of the teeth, very often the affected teeth have been pulled because the tumor has been suspected of resulting from diseased teeth The fungiform type of cancer may protrude as a solid mass, the surface being smooth without noticeable ulceration

In *carcinoma* of the upper jaw there may be a degree of circumscription because an adamantinoma sometimes becomes malignant and protrudes through the gums. Adamantinomas usually can be differentiated roentgenographically.

Sarcoma occurs in the periosteum of the jaws and in the antrums. The early sign of a periosteal sarcoma is the tumorous elevation that is diffuse. The sarcoma most commonly is situated on the lower jaw In this situation it grows more slowly than in the maxilla Sarcoma of the antrum may develop more quickly than a periosteal sarcoma, and may make itself manifest by expanding the bone, then perforating it and spreading to the surrounding tissues Occasionally a sarcoma grows into the nostril and fills it, this development being followed by a foul-smelling bloody discharge. Tumors of this type are highly malignant dangerous growths of poor prognosis

THE TEETH

Dentition. The maxillae and the mandible carry the teeth The temporary or deciduous teeth appear with greater regularity as to order than as to time The permanent teeth arrive as follows first molars, 6 years, incisors, 7 to 8 years, bicuspids, 9 to 10 years; canines, 12 to 14 years, second molars, 12 to 15 years, third molars, 17 to 25 years

Early Dentition. Eruption of the teeth in advance of the usual dates is not of special significance.

Roentgenograms show extensive multilocular rarefaction and pronounced expansion of the mandible. The maxilla is also greatly expanded, but the rarefaction is diffuse rather than multilocular. No other bones are affected. Near puberty, the facial appearance improves, with a progressive decrease in the size of the jaws; by middle age the roentgenologic and facial abnormalities are minimal or absent. Tissue specimens from the jaws show fibrous tissue containing varying numbers of giant cells.

Osteomyelitis of the Jaws. Owing to the variation in the structure of the upper and the lower jaws, osteomyelitis is differently manifested in the two jaws.

In the *upper jaw* the osteomyelitis may be localized about one or more teeth or may affect much of the bone. However, the process rarely extends beyond the alveolar process. The upper jaw is affected by an extension from a tooth or from the frontal sinuses. Rarity of extensive osteomyelitis in the upper jaw is due to a lack of marrow cavity in this bone.

In children, but rarely in adults, infections in an antrum may be severe and the necrosis extend to the alveolar process and the hard palate

In local infections of the upper jaw well-formed spicules of bone may be cast off at once or at intervals of varying length. Only rarely is there an extension to a number of teeth so that a considerable portion of the bone is extruded In such instances the separated part is firm, and is little eroded except in processes due to chemical intoxication, particularly mercury

The *lower jaw* may be affected by an acute process simulating the acute osteomyelitis of the long bones. The localized necrosis due to local infections may remain as such

Local infections of the lower jaw follow infection about the teeth and frequently are associated with the extraction of teeth The wisdom teeth are the chief offenders. The masseter muscles become infiltrated or reflexly spastic, so that the patient cannot open the mouth The edema may involve the submaxillary region and in severe cases suppuration in the deeper planes may occur even to the spread of the infection down the carotid sheath to the mediastinum Spreading to adjacent teeth may occur The removal of the bacterial focus may allow the infection to subside. Infections following injury by certain drugs, notably mercury, arsenic and antimony, may lead to more extensive destruction Even the local use of arsenic in the preparation for filling of teeth may lead to extensive destruction, even to the loss of a part or all of the alveolar process The involvement of the soft parts in local bone infections is usually limited to a local abscess which opens about the gum or beneath the jaw

The marrow cavity in the lower jaw is limited. Its blood supply is enclosed in the inferior dental canal In cases in which the inferior dental artery is occluded there is destruction of a large part or all of the lower jaw, but usually the alveolar process alone is involved, resulting only in the loss of a large part or all of the teeth. Accompanying the involvement of bone there may be chills, fever, pain and swelling of the jaw. The infection may extend to the neck In such cases wide suppuration of the soft parts of the neck is usual and extension down the carotid sheath into the mediastinum may follow In the severer cases death from generalized sepsis may occur

Owing to the density of the bone of the lower jaw, the necrotic bone is extruded more slowly than in the long bones, so that many months, even years, may be required to complete the process of separation

Defective Mobility. *Inability to open or close the mouth may be due to spasm* or paralysis of the muscles of mastication. The masseter, temporal and other muscles concerned in the act of chewing are innervated by motor fibers from the fifth nerve (trigeminus), and spasm and paralysis of these muscles indicate some interference, organic or functional, with the action of this nerve.

The jaw muscles may be tested by desiring the patient to clench the teeth. If the muscles are intact, lateral ridges are thrown up across the face from the malar emi-

Early, extensive or rapid dental caries may be due to rachitis, but occurs also in pregnancy, diabetes and chronic phosphorus poisoning. Usually, however, it is of unknown cause. The influence of carious teeth as a source of irritation or infection causing bad breath and adenitis is obvious

Grinding of the Teeth. Gritting or grinding of the teeth during sleep does not necessarily indicate worms It occurs in children and in neurotic patients and other adult persons who are affected by pain and who for any reason sleep uneasily.

Infections. Infections of the teeth often originate from deeply extending dental caries. Such infections are usually confined to the roots of the teeth and are defined as apical abscesses They are rarely larger than a few millimeters in size.

The infections may not give symptoms In some instances they occur after the tooth has been rendered nonvital by the dentist but more frequently they occur spontaneously. Pain in the affected tooth and swelling and tenderness localized over the area affected are the common manifestations Infections of a more acute character about tooth roots may involve a greater or lesser extent of the adjacent bone and thus cause an osteomyelitis

Tumors of Dentigerous Origin. *Dentigerous cysts* begin insidiously. The patient's attention is not attracted to the presence of the cyst until the expanding jaw produces a deformity. These tumors can be demonstrated on roentgenologic examination. They may become very large and may involve a greater part of the bone, making surgical removal almost impossible because of the softness and fragility of the bone.

Odontomas. Odontomas, tumors of toothlike structure, are closely allied to dental root, or radicular, cysts Although they represent a more mature tissue development, they often complicate radicular cysts. A dense thickening of the jaws represents the physical findings, which point to the occurrence of odontoma. The diagnosis is confirmed by roentgenologic examination.

Adamantinomas. These are epithelial tumors of the jaw originating from epithelial remnants of the enamel They occur in young persons and produce expanding bone tumors which are first demonstrated by roentgenologic examination. Under ordinary circumstances adamantinomas are noninvasive and nonmalignant tumors.

THE GUMS

A *narrow band of bright red inflamed gum tissue* surrounding the neck of the tooth, primarily on the buccal surface, is a characteristic observation in all species of mammals. It is not a recent disease, nor is it the result of so-called present-day perverted methods of preparing and seasoning foodstuffs Mankind now enjoys the greatest variety of the most wholesome foods that has ever been available to any animal This narrowed band of inflamed gum tissue, more pronounced on the buccal surface, bleeds readily on slightest injury and is comparatively free from pain. *Gingivitis* is a more profound infection of the gums than this reddened tissue surrounding the tooth. It is an extension of this normally reddened margin.

Pallor of the gums is noticeable in all forms of anemia *Red and spongy gums* may be caused by carious or illkept teeth attended with abundant tartar. Spongy, red and bleeding gums, perhaps ulcerated, occurring in artificially fed infants may be due to scurvy A similar condition in an older person may be the result of scurvy or combined vitamin deficiencies.

Swollen or spongy gums are met with in many debilitating disorders such as leukemia, pulmonary tuberculosis, diabetes and purpura. Ulceration along the line of the gums, rarely extending to the cheeks or tongue, is particularly characteristic of ulcerative stomatitis. Finally, localized or general redness and swelling may attend the eruption of the teeth and poisoning by chemicals and heavy metals.

Diseases of the Gums. *Acute Ulceromembranous Gingivitis* (*Trench Mouth*) This disease often is called Vincent's infection or trench mouth. The dis-

Delayed Dentition. The most important cause of delay in dentition after the age of 15 years is rachitis, together with other conditions or diseases involving malnutrition, particularly those occurring in the first 5 or 6 months of the infant's life. The delay, if observed, is more significant of the past than of the present status. A late appearance of the teeth may be indicative of cretinism.

Difficult Dentition. There has been much difference of opinion with regard to the influence of teething in causing disease.

Anomalies of Dentition. There may be a congenital absence (anodentia) of some or all of the teeth, or a production of more than the normal number. Supernumerary teeth in abnormal locations (for example, the palate) arise from ectopic tooth primordia which have been displaced. A third dentition has rarely occurred. Sometimes fourth molars develop behind the wisdom teeth. Teeth have been observed in which, owing to a defect of the enamel organ, the enamel was wanting Imperfect teeth are frequently associated with harelip Epithelial remnants of the dental lamina may give rise to cysts of various

in the edge, it may be evidence of inherited syphilis (Hutchinson's teeth). These teeth are likely to be small, to be placed somewhat irregularly, and to stand apart from one another If keratitis and disease of the middle ear coexist, a presumptive diagnosis of syphilis can be made.

Dentated, Furrowed or Pitted Teeth. If the edges of the teeth are *dentated,* malnutrition is likely to be the cause. *Grooves* or *furrows* running transversely across the teeth are indicative of an acute illness during infancy or childhood sufficiently severe to interfere with nutrition of the teeth. *Pitted* teeth, the molars exhibiting the greatest changes, are caused by exposure to fluorine in the water.

Loosened Teeth. Loosening of the teeth in their sockets is associated with spongy, ulcerated or bleeding gums and is often a familial manifestation Movability of the teeth usually is due to prolonged fevers, pyorrhea alveolaris, old age, mercurial stomatitis, scurvy, purpura haemorrhagica, phosphorus poisoning or gangrenous stomatitis.

Caries. The cause of dental caries is controversial Some believe that the structure of the tooth and metabolic and nutritional factors are the primary causative factors in tooth decay Others believe that local factors in the mouth such as bacterial acids, the physical state of the food, mechanical abrasion and a lack of protective action of saliva are the causative factors of tooth decay.

A clear relationship between salivary amylase and the incidence of dental caries seems to exist In persons without dental caries hydrolysis of starch by saliva requires approximately 45 minutes for completion The saliva of those with 4 to 6 cavities will complete the hydrolysis more quickly Without exception the rate of starch hydrolysis increases in direct parallelism with the number of cavities

The presence of fluorine in drinking water seems to decrease the number of cavities (see Fluorine Poisoning, Chapter 19).

Recent investigations cited by Turner and Crane appear to support the importance of local factors, particularly bacterial acids, as a primary causative agent in tooth erosion Furthermore, current studies emphasize the relation of dietary carbohydrate intake to the formation of acids by the oral bacterial flora. The restriction

production of organic acids, particularly lactic acid, by this microorga- sponsible for erosion of the teeth Excessive amounts of acids in the mouth can cause dental erosion; this has been shown in experimental animals ingesting certain carbonated beverages or dilute acid solutions and in patients taking excessive amounts of lemon juice for therapeutic purposes.

will not cure the lesion. If the lesion continues after the tooth has been pulled, it should be suspected of being malignant

THE TONGUE AND THE FLOOR OF THE MOUTH

THE TONGUE

Inspection of the dorsal surface of the tongue is a part of the clinical examination which seldom was neglected by earlier physicians. Perhaps never has so much been said about so little as in the nonsense written about appearances of the tongue as presenting evidence of diagnostic significance in many different diseases. In general, the tongue should be investigated, top and bottom, with reference to its color, dryness and size, palpated for lesions, and tested for its mobility Occasionally a worthy bit of diagnostic information will thus be perceived concerning the physical status of the tongue itself.

The mucous membrane which covers the tongue is modified skin Over the dorsal surface of the tongue are papillae. The filiform papillae are the smallest and cover the anterior two thirds of the tongue The fungiform papillae are larger and are scattered on the dorsum, sides and tip of the tongue and are set among the filiform papillae. The circumvallate papillae, seven to twelve in number, form an anteriorly curved row at the base of the tongue. In the median line, posterior to the curved row of circumvallate papillae, is the foramen cecum, which is the upper extremity of the remains of the thyroglossal duct. It is sometimes patulous for a short distance

On the posterior portion of the tongue, behind the circumvallate papillae, on each side of the median line, is a mass of adenoid tissue which forms the lingual tonsil

In the middle of the dorsum of the tongue is a furrow, caused by the septum binding the middle of the tongue down and allowing the muscles to rise on each side.

Anomalies. Reduction or absence of the tongue, referable to developmental arrest, and bifid and trifid tips, through persistence of the unfused apical components, are recorded

The commonest of all deformities of the tongue observed soon after birth is tongue tie, a fixation of the tip of the tongue to the floor of the mouth by a frenum which is too short When the fixation is extreme, the infant may not be able to nurse until the frenum is cut enough to loosen the tip of the tongue

Color and Pigmentation. The color of the tongue, as distinguished from the color of its coating, is of some diagnostic value The most frequent abnormal coloration of the tongue results from either food or drink The tongue is pallid in anemia and bluish in cyanosis A bright red tongue may be due to the exanthems, particularly in the early stage of scarlet fever, or to inflammation of the tongue itself (glossitis), it differs from the darker, reddened tongue of the deficiency states Petechiae, ecchymoses and infarcts may be found on the tongue, where they have the same significance as if found elsewhere Dark purple or blackish deposits of pigment may indicate an admixture of racial characteristics, or an old glossitis, or may constitute the discolorations of Addison's disease In jaundice the tongue is yellowish, with the yellow tinge particularly marked on the under surface of the tip. A series of clearly outlined yellowish white spots along the edges of the tongue is characteristic of xanthelasma

Uniform discolorations of the tongue and its coating may be caused by the ingestion of various substances, corrosive or noncorrosive Ammonia, bichloride of mercury, and sulfuric, carbolic and oxalic acids whiten the tongue, hydrochloric, nitric and chromic acids produce a yellow color. Potassium and sodium hydroxide redden the tongue Among the noncorrosive drugs and foods, bismuth, charcoal and iron stain the tongue black, wine, fruits and berries color it red or purple; and rhubarb, tincture of opium, tobacco, licorice and chocolate stain it brown or black.

Cross estimated that discoloration of the tongue constitutes at least 30 per cent of all oral reactions in patients taking penicillin orally. The discoloration appears as

ease is caused by invasion of a mixed infection, primarily represented by *Fusobacterium plauti-vincentii* in association with *Borrelia vincentii* At the onset the patient is aware of an uncomfortable feeling and salivation, and the tips of one or more of the interdental papillae on the buccal surface begin to swell They assume a livid, grayish color and become the sites of small, flat, punched-out ulcers that undergo necrosis The necrosis may destroy the gingivae down to the alveolar process. A strip of brown colored membrane may cover the affected gingival margin Removal of the membrane leaves a bleeding surface. The inflammation spreads rapidly, but only in severe cases is the palatal surface of the gingivae affected Contact ulcers form on mucous membranes of the cheek or on the borders of the tongue The disease may spread posteriorly to the tonsils The mandibular lymph nodes are painful and enlarged There may be fever, the temperature up to 104 F (40 C) The sense of taste may temporarily be completely lost

Trench mouth must be differentiated from avitaminosis, scurvy, pellagra and blood dyscrasias such as leukemia. Although there may be extensive and widespread destruction of the gum margins, the prognosis in trench mouth is good

Pyorrhea Alveolaris. There is no known systemic disease that will cause pyorrhea alveolaris, but there are two factors that produce the condition. an abnormal occlusal stress on the articulating tissue of the infected teeth, and coexisting disease that lowers the vitality of this articulating tissue. Pyorrhea alveolaris always presents deep pockets containing suppurating granulation tissue with, sooner or later, loosening of the teeth The patient usually presents himself for general examination to find the cause of receding gums In the aged the periodontium often is smooth and atrophied This atrophy, however, may occur at an early age; the condition should not be mistaken for pyorrhea alveolaris.

Abnormalities and Tumors. ***Hypertrophy.*** This is a slowly developing process, and usually a great amount of deformity is present before the patient is aware that the gums actually are getting larger There are, by the time awareness is aroused, a nodulated enlargement of the gums and an irregular arrangement of the teeth On palpation the nodulations are densely hard The mucous membrane is not affected

Diffuse Fibromatosis of the Gingivae. Diffuse fibromatosis of the gingivae may be hereditary No symptoms may occur until the fibromas become malignant and cover both sides of the alveolar processes of both jaws and even cover the crowns of the teeth By this time the teeth themselves may be crowded out of position The surface of the fibroma is light pink and is often roughened by papules and ridges of proliferative gum tissue The tumors often are large enough to distort the facial contour.

Epulis. An epulis is a fibrous tumor of the gum An epulis on the lower jaw is small and of slow growth An epulis of the upper jaw adjacent to a molar tooth or a bicuspid tooth is usually large when first seen The surface of the tumor has the color of the adjacent mucous membrane The mucosa is usually continuous over the surface of the tumor Occasionally epulides are bluish red and vascular in appearance Epulis recurring after one or two removals may become malignant

Granulomas of the Alveolar Borders. Dental granulomas develop from sites of irritation and are the result of infection. The usual history is that the granuloma or tumor has developed within recent weeks, within one or two months at the most The tooth on which the granulomatous tissue forms may be free of disease, but usually the deposits on its surface irritate the adjacent gum

These lesions begin as soft growths of the gum adjacent to a tooth or several teeth. If one tooth is involved, the granuloma usually is not a large one As these tumors grow older, they become harder and are usually less red than the surrounding tissue. Removal of the tooth, unless the granulomatous tissue also is removed,

plies the muscles which fix and depress the hyoid bone in chewing and swallowing.

If the cortical connections of the nucleus are involved, there will be paralysis but no atrophy; or if atrophy is present, it is slight. Contraction of the tongue due to the absorption, under treatment, of a lingual gumma may appear somewhat like paralytic atrophy.

Spasm. Spasm of the tongue is a rare symptom It may be tonic, in which case the tongue is contracted and rigid, or clonic, in which case the tongue jerks and twitches irregularly or is protruded and retracted rapidly. The movements usually involve both halves of the tongue, but may be unilateral

When clonic spasm of the tongue exists, it usually is a part or symptom of chorea, hysteria or epileptic convulsions, or is associated with mimic tic. Stuttering is a spasmodic affection of the lingual muscles. A curious disorder reported in those who use the voice incessantly, for example solo singers, is a spasm of the tongue on attempting to speak, a condition analogous to writer's cramp. Lingual clonic spasm is an occasional symptom in disseminated sclerosis and general paralysis Reflex irritation of the fifth nerve has been held responsible for lingual spasm and, in some instances, disease of the central nervous system produces it.

Tonic spasm of the tongue is indicative of hysteria or reflex irritation through the fifth nerve, occurring in nervously weak and debilitated persons. It may coexist with tonic spasm of other voluntary muscles

Tremor. A coarse tremor or trembling of the tongue is most frequently symptomatic of chronic alcoholism and is present in delirium tremens, it usually is present in brominism, and it may exist as a part of paralysis agitans A fibrillary tremor or fine twitching of the muscular bundles of the tongue may be seen in disseminated sclerosis, in general paralysis, and in bulbar paralysis when the lingual muscles begin to atrophy The tongue trembles in neurotic persons, particularly when they are excited or agitated.

Paralysis. If one side of the root of the tongue is higher than the other, and if when the tongue is protruded it deviates toward the same side, unilateral lingual paralysis exists There are likely to be some interference with speech and a slight difficulty in chewing and swallowing. If the tongue lies motionless in the floor of the mouth, the patient being unable to protrude it, and the functions of speech, mastication and deglutition are greatly impaired, there is total lingual paralysis. In both cases there may or may not be atrophy and fibrillary twitching. The absence of atrophy indicates a cortical or supranuclear lesion; the presence of atrophy indicates a nuclear or infranuclear lesion

Lingual paralysis, with atrophy of either one or both sides of the tongue, according to the situation or extent of the lesion, may exist as a symptom of the following conditions. general paralysis, chronic lead poisoning, embolism or thrombosis of the vascular supply of the basal nuclei, basal meningitis or tumor of the base, syphilitic disease or other disease of the bone at the base of the skull or of the first cervical vertebra, tumor of the upper portion of the spinal cord, and wounds of the neck

Inflammations. Inflammations of the tongue are likely to be diffuse. Their cause often is obscure. Lingual inflammations are characterized by pain, burning and swelling These symptoms may remain for days and gradually subside without leaving a trace. On examination the tongue is red and thick, the thickening being evident on palpation The increased heat of the tongue is readily discernible by the palpating fingers If abscess formation has occurred, a fluctuant region may be located on palpation

The tongue may appear enlarged when the floor of the mouth becomes inflamed Examination reveals edema under the tongue or under the chin Suppuration with abscess formation may follow.

early as 2 days, as late as 9 days and on an average of 4 days following the use of penicillin.

The Black Hairy Tongue. Black hairy tongue is an uncommon disorder and its cause is unknown It is thought in some instances to be due to a congenital abnormality which develops in later life. *It is a pigmentation and involves principally* the back of the tongue, the central furrow and portions of the pads, leaving the sides and tip unaffected. The color varies from yellowish brown to black.

Histologically, the filiform papillae are hypertrophic and hyperkeratotic and are the origin of hairlike filaments that may grow as long as ½ inch (1.27 cm.). The papillae become densely matted, and deposition of pigment takes place. The pigment is considered to be derived from food, wines, tobacco, iron and mercury, and mouth washes that contain oxidizing or reducing chemicals (Wolfson)

Black tongue has also been caused by the filamentous mycelia of actinomycosis which have been cultured from the tongue.

Dryness. The term appearance used with reference to the tongue usually relates to the character of the coating which may be present or to the disappearance of the coating and, particularly, to its degree of moisture The coating consists of accumulated epithelium, microorganisms and food detritus. Dryness of the tongue, when not caused by mouth breathing or coma, is of very considerable importance as an indication of general dehydration and prostration.

A thin, white, even furring of the tongue is normal in many healthy persons, *particularly those who are in the habit of smoking or of drinking milk*, and in mouth breathers. Such a coating is always present in moderately febrile states.

A tongue covered with a white fur through which project greatly swollen and bright red fungiform papillae is seen most frequently in acute infections, either generalized or limited to the tongue. This is not necessarily pathognomonic of scarlet fever

Size. Great enlargement of the tongue is easily determined. A slight increase in size can be assumed to be present if the edges of the tongue are indented by the teeth, the indentations existing only if the tongue is swollen beyond its normal limits

Macroglossia. This is a rare lesion of obscure origin Usually in such cases an abnormally enlarged tongue is observed in a child soon after birth A tongue of this type seems to grow slowly, and the whole organ is involved in the processes of enlargement. The tongue is firmer on palpation than the normal tongue. It may become so greatly enlarged that it lacks the capacity to move, and there may be local ulcerations where it has rubbed against or hung over the teeth

Enlargement of the tongue and a feeling of stiffness in it may accompany a general or regional amyloidosis Enlargement of the tongue occurs in acromegaly and in myxedema If associated with inflammatory symptoms, *the enlargement is* due to acute glossitis. If associated with urticaria or angioneurotic edema, it is allergic in origin Tumors of the tongue also are responsible for an irregular and sometimes great increase in its size.

Shrinking or Atrophy. The tongue is small after a profuse hemorrhage and may become noticeably lessened in size during starvation

In atrophy of the tongue, a condition which is due to some affection of the hypoglossal or motor nerve of the tongue involving its nucleus or its peripheral portion, the mucous membrane of the tongue is thrown into folds and the organ has [illegible] The atrophy is always conjoined with paralysis, and the [illegible] both lateral halves of the tongue accordingly as [illegible] Unilateral atrophy of the tongue sometimes is associated with facial hemiatrophy. Unilateral hypertrophy of the tongue sometimes occurs in congenital hemihypertrophy.

Spasm, Tremor and Paralysis. The motor supply of the muscles of the tongue is for the most part derived from the hypoglossal nerve. The same nerve also sup-

or both sides of the neck may become involved from a malignant growth in any portion of the tongue. Lymph nodal involvement is not always palpable.

The diagnosis is made on the basis of the histologic structure of biopsy tissue. The prognosis is usually unfavorable.

THE FLOOR OF THE MOUTH

On turning up the tip of the tongue a fold of membrane, the frenum linguae, is seen extending from the under surface of the tongue to the floor of the mouth beneath. In newborn children this fold of mucous membrane appears sometimes to be too short, hence the term tongue-tied. This anomaly may persist throughout life if not properly treated.

Between the teeth and the tongue, parallel to the alveolar process, is the sublingual ridge, formed by the sublingual salivary gland. On the median side of the sublingual gland are the lingual nerve and the submaxillary duct (Wharton's duct), and on each side of the frenum, on the anterior aspect of the sublingual ridge, is a papilla into which the duct opens Opening into the submaxillary duct, or by a separate duct into the same papilla, is the duct of the sublingual gland (the duct of Bartholin)

The Submaxillary and the Sublingual Salivary Glands. These glands present infections and tumors almost identical with those observed in the parotid glands. The submaxillary glands, like the parotids, may be absent or displaced, or there may be accessory glands

Infections and Inflammations. These disorders of the sublingual and the submaxillary salivary glands are not unusual occurrences The glands may be swollen during an epidemic of parotitis, but commonly they are affected in fevers and in serious illnesses much as the parotid glands are affected. Occasionally there is a low-grade inflammation of the sublingual and submaxillary glands which causes swelling of the ducts and obstruction to the flow of saliva during a meal Soon after eating, the patient becomes aware of a swelling under the chin along the inside part of the lower jaw. A swelling of this type may be painful, but it usually subsides within a few hours; it may not recur, or it may become rather annoying and recur at frequent intervals The swelling is due to obstruction of the duct by a tenacious secretion and subsequent edema and pressure.

Stones. Formation of sialoliths in the submaxillary ducts and the sublingual ducts is much commoner than in the parotid ducts

Salivary calculi usually originate within the gland structure in the form of small concretions which are carried along with the salivary current to become lodged in the gland duct. Here they become enlarged by deposits of bacteria and phosphates. Any of the salivary glands or ducts may be the site of calculous formations, but the most frequent location is Wharton's duct, after which, in order of frequency, the submaxillary glands, the parotid glands and Stensen's ducts.

The symptoms depend on the size and situation of the stone. If it lies within the gland structure, the patient may experience only a mild intermittent feeling of irritation and discomfort in the affected region together with moderate swelling If, however, the stone is in the duct, the symptoms may be severe, characterized by a sudden sharp pain when the salivary flow is stimulated and rapid, and painful distention of the gland In the course of 12 to 48 hours an inflammatory reaction may occur, due to the retention of infected secretions. General malaise may ensue.

The floor of the mouth may be dry, and frequently no saliva will be found flowing from the obstructed duct when the patient is asked to suck a piece of lemon. Palpation of the duct may express pus or reveal the location of the stone. Pus may be found in the floor of the mouth, together with swelling of the tissues along the course of the duct with deviation of the protruded tongue when the submaxillary gland is involved A probe passed into a salivary duct may fail to locate the stone If the calculus is large enough to cause obstruction, and particularly when it con-

Eczema. Eczema of the tongue gives rise to a condition variously known as *geographic tongue*, annulus migrans or wandering rash Ring-shaped patches, red and denuded of epithelium, are seen on the tongue, and under observation are seen to spread at the edges while healing at the center, coalescing and forming irregular areas with curved outlines Usually there is little or no discomfort from this condition

Scars, Fissures and Ulcers. Scars. Scars on the tongue may be the result of healed ulcers, of chewing the tongue during attacks of epilepsy or bulbar palsy, of accidental biting of the tongue during restless sleep or in careless chewing of food, or of a fall when the tongue is between the teeth.

Fissures. Fissures of the tongue, aside from the normal median longitudinal one, also are often of normal occurrence, especially in elderly persons. Deep fissures of the tongue are seen in Mongolian idiots. In other subjects fissures are often significant of chronic glossitis. Very deep inflamed fissures are often due to glossitis, and in an occasional instance are of syphilitic origin. Fissures or losses of substance at the edges of the tongue are usually due to deficiency states or to rough or broken teeth

Leukoplakia lingualis (ichthyosis linguae, leukoma, leukokeratosis, buccal psoriasis) is manifested by slightly elevated, thickened patches of irregular shape, not ulcerated, white and smooth on palpation, which sometimes show a tendency to fissure. They may furnish, in 1 case in 10, the starting point of an epithelioma

Ulcers. Acute and painful ulcers of the tongue are often due to aphthous stomatitis, less often to the ulcerative form of stomatitis. In chronic superficial glossitis shallow, red, glazed, denuded areas occur on the surface of the tongue. Multiple ulcers, gray, indolent, stellate, and associated with enlarged cervical lymph nodes, may be tuberculous and are almost always secondary to tuberculous disease of the lungs. Somewhat similar multiple ulcers may be syphilitic, but in such cases the anterior cervical lymph nodes are rarely enlarged Multiple small ulcers, preceded by vesicles, occur in smallpox, varicella, measles and erysipelas, as well as in pemphigus, herpes and eczema of the tongue

A single lingual ulcer with a hard base, associated with enlarged cervical lymph nodes, may be either the initial lesion of syphilis or an epithelioma When syphilis exists, the age of the patient is usually less than 40 years. The lesion is on the tip of the tongue, is not very painful and improves under treatment A mucous patch may become ulcerated, or a gumma of the tongue may break down, forming a deep sore A single ulcer, if opposite a rough or jagged tooth, may be simply the result of continued trauma, but the presence of an irritating tooth does not exclude epithelioma or syphilis

An *ulcer* on the *frenum linguae* may occur during the course of severe coughs, such as pertussis, from the thrusting of the undersurface of the tongue against the lower incisors habitually or during paroxysms of coughing.

Tumors. Benign Lingual Tumors. Any kind of benign tumor of the tongue is uncommon in adults Papillomas, small in size, are the commonest of the benign tumors. Fibromas, cysts, lipomas and hemangiomas may be encountered.

Malignant Lingual Tumors. Carcinoma of the tongue is commoner in men than in women, and commoner in middle-aged men than in either the young or the old.

Carcinoma of the tongue begins on the surface of the tongue either by a change in the epithelial covering or in fissures or ulcers at its edges. Some carcinomas of the tongue begin in leukoplakial spots, a few begin as benign papillomas, and still a few more begin in ulcers caused by broken teeth or defective dental structures. A greater number, however, just begin as sore places and continue as enlarging ulcers.

The lymphatic vessels from the mucous membrane and deep tissues of the tongue have apparently only a single outlet, so that the lymph nodes on either side

fluids through the nose on attempting to swallow, and if there is failure to pronounce correctly certain sounds; for example, the patient says "beng" for "beg." Inspection of the soft palate during the utterance of the long "ah" sound will show under normal circumstances that both sides of the palate arch upward. If the whole palate remains motionless during phonation of "ah," there is bilateral paralysis; if but one side moves, paralysis is unilateral.

Paralysis of the soft palate is most commonly due to diphtheritic neuritis or poliomyelitis, but is also caused by bulbar paralysis, brain tumors, basal meningitis and vertebral caries.

Anesthesia of the Palate and the Fifth Cranial Nerve. *Anesthesia* of the hard and soft palates indicates disease involving the second division of the *fifth nerve*.

The motor portion of the trigeminus supplies the muscles of mastication, namely, the two pterygoids, the temporal, masseter, mylohyoid, and anterior belly of the digastric

The sensory portion of the trigeminus affords sensation to the face, conjunctivae, nose, frontal and maxillary sinuses, teeth, palate, tongue, part of upper pharynx, external auditory meatus, and the scalp as far back as the vertex. It may or may not supply the sense of taste on the anterior two thirds of the tongue.

The motor functions of the trigeminus are tested by having the patient clench the teeth firmly, while the temporal and masseter muscles are palpated in order to observe their contraction. Also have the patient open his mouth. If the muscles on one side fail to contract, and the opened jaw deviates toward the paralyzed side, there is unilateral paralysis due to disease affecting at least the motor fibers of the inferior maxillary division of the trigeminus. Spasm of these muscles constitutes trismus or lockjaw

The sensory functions of the trigeminus are examined in the ordinary manner Whether one or all of its divisions are involved may be determined by comparing the areas of anesthesia found with its distribution If there is complete unilateral anesthesia, the patient when drinking can feel the contact of the cup or glass on one side only, affording a sensation as if half the vessel were missing. The sense of taste is partly conducted through the medium of the trigeminus There are certain inflammatory (herpes zoster), vasomotor (flushing, pallor), and secretory (lacrimation, salivation) disturbances which may arise from disease of the trigeminus because of the fact that it supplies the lacrimal and salivary glands with secretory fibers and is also the channel by which vasomotor fibers run The trigeminal nerve is involved in neuralgias and migraine. Trigeminal anesthesia is seen in hysteria, and in various forms of organic disease which, to a greater or lesser extent, involve the cranial nerves or the cranial nerve centers. Areas of cutaneous anesthesias, when the cutaneous nerves of the head and face are involved, are shown in Figure 4-1

Tumors. Slowly developing tumors of the palate are exostoses and ecchondromas They are situated in the midline, grow very slowly, and cause no trouble except that the patient is conscious of their presence The appearance of the tumors is characteristic They feel smooth and hard unless they are myxomatous or malignant.

THE FAUCIAL TONSILS

The tonsils are oval, and when normal in size, project but little if at all beyond the pillars of the fauces. They contain several recesses or crypts formed by the folding inward of the mucous membrane The walls of the crypts contain lymphoid tissue and mucous glands Extending from these crypts are pockets known as follicles These follicles may become sealed from inflammation which leaves palpably hardened areas in the tonsils

Acute Tonsillitis. Tonsillitis is most frequently met with between the ages of 10 and 30 years. The disease sometimes occurs in children less than 10 years of age and in adults of more than 50 years of age Tonsillitis accompanies many acute

tains calcium salts as its chief constituent, it is usually demonstrable in a roen genogram

Cysts. The term ranula generally is applied to any cyst in the floor of the mou that is due to obstruction of a duct of either a mucous gland or a salivary gland. Th cysts arise just behind the lower incisor teeth and may be due to involvement the incisor gland (glandula incisiva), but most commonly they are due to obstru tion of the excretory ducts of the sublingual glands. Among ranulas have been i cluded retention cysts as well as congenital inclusion cysts. Ranulas must be di tinguished from dermoid cysts The dermoid cyst has a thicker feel, more firm c palpation, and it often pits on pressure.

Tumors. Submaxillary tumors begin as small swellings beneath and medial t the border of the jaw just in front of the angle of the jaw. As a tumor of this typ becomes larger, it may occupy a considerable region of the neck. It is impossible t tell whether the growth springs from the submaxillary gland or the sublingual glan until the affected gland is identified

One of the common tumors of the submaxillary gland, as of the parotid glanc is the mixed tumor. The hard but elastic feel of these growths is characteristic. Th tumor is easily palpated by one finger of one hand on the floor of the mouth, wit the other hand under the chin. If the tumor has become malignant, it is fixed mor closely in its position

Carcinoma of the Floor of the Mouth. This lesion usually is an ulcer witl hard borders It often is found accidentally before it gives the patient any symptoms Some growths of this type are small rounded masses circumscribed and somewha movable, large tumors may form, however, filling the whole floor of the mouth an bulging into the neck

THE PALATE

The superior and lateral boundaries of the oral cavity and the differentiation of th nasal and oral cavities are the result of fusion of the two lateral maxillary processes o the first branchial cleft and the medial frontonasal process which descends from th anterior part of the head in the embryo Failure of fusion of these processes, in part o entirely, in embryonic life results in one or another variety of cleft palate *Cleft palat is discussed with cleft lip*

The anterior and posterior arches of the palate and the uvula are plainly visible The anterior pillar extends from the soft palate to the tongue and is formed by the palatoglossus muscle. The posterior pillar extends from the soft palate downward to the sides of the pharynx and is formed by the palatopharyngeus muscle In front of these arches, and extending from the roof of the mouth opposite the posterior edge of the last molar tooth downward to the posterior edge of the alveolar process of the lower jaw, is an elevation of the mucous membrane which shows the line of junction of the hard and soft palates

Torus palatinus is a protuberance of the hard palate at the line of closure of the maxillary sutures These swellings are unimportant clinically They are often of concern to the patient.

The anterior three fourths of the roof of the mouth is formed by the hard palate and the posterior one fourth by the soft palate

Vesicles arranged in annular shape on the soft palate or perhaps on the pharyngeal wall, and attended with a disproportionate amount of pain, are viral herpes of the same sort that occurs elsewhere on the mucous membranes of the mouth When these vesicles rupture, small ulcerations follow and constitute the commonest acute ulcerations of the palate Chronic ulcers of the palate are often of syphilitic origin.

Perforation of the soft palate or its *adhesion*, either partial or complete, to the posterior pharyngeal wall, may be the result of any severe infection or due to syphilitic ulceration or diphtheria

Bilateral paralysis of the soft palate is to be suspected if there is regurgitation of

portion of the membrane or of a swab from the surface of the tonsils. The presence of Klebs-Löffler bacillus (*Corynebacterium diphtheriae*), when culture is made on the proper media, indicates diphtheria

In regard to the relationship of acute tonsillitis and scarlet fever, see Streptococcal Infections in Chapter 17.

In cases of uncomplicated tonsillitis the outlook is always favorable. The disease runs its course in about a week. Peritonsillar abscesses or quinsy may occur and when they do develop, they greatly increase the discomfort of the patient. In peritonsillar abscess or quinsy the prognosis is more guarded, especially because of the possibility that the more virulent infection may produce septicemia or Ludwig's angina.

Corynebacterium diphtheriae (Klebs-Löffler Bacillus) and Diphtheria. The causative organism of diphtheria is of the order Eubacteriales Buchanan, family Corynebacteriaceae Lehmann and Neumann, genus *Corynebacterium* Lehmann and Neumann, and species *Corynebacterium diphtheriae*.

The optimism that prevailed during the first three decades of the twentieth century with regard to the successful therapeutic control of diphtheria yielded to pessimism and perplexity when numerous instances of malignant diphtheria occurred in central Europe, for these cases were wholly refractory to routine methods of serum therapy Later the instances of *malignant diphtheria* proved to be a special type, due to *Corynebacterium diphtheriae gravis* Since this division was made, the name *Corynebacterium diphtheriae mitis* has been employed to designate the nonmalignant strain.

The extracts of the gravis strain produce necrotizing and edematous lesions resembling the local reactions to potent staphylococcal or streptococcal toxins The main product from gravis strains is an endotoxin analogous to the Duran-Reynals spreading factor formed by certain invasive strains of pyogenic cocci The severe lesions of malignant diphtheria are due to the synergic effects of classic diphtheria toxin with gravis endotoxin The gravis strains of diphtheria may account for the exceedingly large quantities of antitoxin required for the successful control of the symptoms in an occasional patient who has diphtheria.

There are conferred active immunity and passive immunity to diphtheria Active immunity now is conferred by the use of especially prepared toxoid solution, of which one injection produces immunity

The diphtheria organisms are transmitted by droplets, food, handling of articles in common use, such as toys, and by contact directly or indirectly through clothing The germs can live for weeks on toys and clothing and on various household utensils that are not in common use

The carrier rate increases with the beginning of cold weather. The presence, in the nose of a subject, of bacilli that appear morphologically to be those of diphtheria is not enough to justify giving the person the stigma of carrier and enforcing isolation for treatment The bacilli should be isolated and their virulence proved bacteriologically before the subject is labeled a diphtheria carrier and before isolation is advised

Susceptibility of the individual to diphtheria can be determined by tests If susceptibility exists, prophylactic treatment can be given that usually suffices for control.

Schick Reaction The blood of the majority of normal adults contains a small amount of diphtheria antitoxin, a fact which probably accounts for resistance of many persons to diphtheria The presence of the antitoxin may be easily detected by means of the Schick reaction A standardized diphtheria toxin is diluted in physiologic salt solution so that 0 1 ml of the solution contains 1/50 of the minimal lethal dose for a guinea pig This dose is injected intracutaneously If the blood of the subject tested has less than 1/30 unit of antitoxin per milliliter, a positive skin reaction appears in from 24 to 36 hours and persists for 4 or 5 days or more. A positive reaction consists in a slight infiltration of the skin surrounded by a red areola 1 to 2 cm in diameter. Positive reaction indicates susceptibility, negative reaction indicates natural immunity to diphtheria. The naturally immune person, however, may harbor the bacilli and be a carrier; it follows, therefore, that many carriers may give negative reaction

Negative reactions to the Schick test are obtained in 9 out of 10 of the newborn, but become less frequent in children up to the second to the fifth year As children grow

illnesses. It is present in the initial stage of measles and scarlet fever. It is frequently present in diphtheria and in secondary syphilis. Water and milk may carry infective organisms for tonsillitis Tonsillitis is sometimes infectious and not infrequently epidemic Hemolytic streptococci, often in pure culture, have been found during epidemics of acute tonsillitis in military camps and in civilian practice. The diplococcus of pneumonia is said to be responsible for less than 10 per cent of cases of acute tonsillitis, and to the *Hemophilus influenzae* organism (bacillus of Friedlander, *Klebsiella pneumoniae*) is attributed a very large percentage of benign membranous tonsillitis

If the tonsillitis is limited to the catarrhal variety, the surface of the tonsils shows the changes common to inflammation of the mucous membrane. In other cases, the so-called lacunar variety, the morbid changes are confined mainly to the crypts In the so-called parenchymatous tonsillitis there is congestion of the whole tonsil

SYMPTOMS. An attack of tonsillitis is not necessarily ushered in with symptoms referable to the throat. There may be such symptoms as fever, sometimes chills and fever, the temperature reaching 102 to 103 F (38 9 to 39.4 C) and in severe infections as high as 105 F (40 6 C) In most instances of tonsillitis the local symptoms make themselves felt at once The illness begins with a feeling of fullness in the face and the throat, amounting soon to sharp pain which extends up to the ear and is generally augmented on attempt to swallow There may be so much pain on trying to swallow that the patient quits eating and drinking. The voice becomes thick and muffled, the senses of smell and taste are suspended, and there may be deafness from eustachian catarrh. Headaches, backaches and pains in the arms and legs are of common occurrence

EXAMINATION. The lymph nodes at the angle of the lower jaw are swollen and in most cases are very tender, so that the head is held stiffly The throat is often difficult to examine in those who have acute tonsillitis, for the pain is intense when they try to open the mouth, and consequently a view of the back of the throat is often facilitated by the use of a head mirror The inflammatory process extends to the anterior faucial pillars, the uvula, soft palate and pharynx, where the evidence of pharyngitis may also be apparent The congested surface of the tonsils is often spread over irregularly with debris which occludes the orifices of the tonsillar crypts This debris may accumulate and as time passes may form a white, grayish or dirty yellow membrane This membrane, in contrast to that accompanying diphtheria, is readily separated from the tonsil and does not leave a bleeding surface when it is removed The swelling produces obstruction of the circulation in the region of the tonsil and leads to edema in the more relaxed tissues on the posterior wall of the soft palate, which may be seen hanging down in a translucent bag on each side of the uvula The soft palate may become so impeded in its action that the voice becomes almost unintelligible, and the attempt to swallow liquids may be followed by regurgitation through the nostrils

Tonsillar abscesses are rare, but when they do appear they discharge their purulent contents into the pharynx without ill effects

DIAGNOSIS. The diagnosis generally presents no difficulty. Acute follicular tonsillitis must be differentiated from diphtheria. Diphtheria generally is more gradual in its onset and it is more likely to begin on one side, or at least it does not start on one side and then develop on the other, as does tonsillitis There are less pain and fever in diphtheria. The mouth is opened more easily and the throat, with the characteristic adherent, spreading, false membrane, may be viewed more easily in diphtheria than in follicular tonsillitis. The false membrane in diphtheria generally invades the soft palate and uvula and often spreads to the larynx, postnasal space and the nose The younger the patient, the more likely is the condition to be diphtheria. In doubtful cases the final diagnosis is to be made after culture of a small

whereas in others there is a chronic parenchymatous hyperplasia in which the tonsil is soft and friable, in still others there is a slow fibroid degeneration, an increase in the connective tissue stroma In tonsils with fibroid degeneration there may be cyst formation or the deposit of calcareous masses.

Of paramount importance is the fact that the size of the tonsil is not a criterion of an infectious disease. Some of the largest tonsils give rise to the least local inflammatory trouble, whereas small tonsils which have adhesions about their borders, and the remains of tonsils which have been imperfectly removed surgically may be the source of serious illness of the patient. The tonsil is more to be suspected as a septic focus when creamy pus can be expelled regularly from the fossa, or when a congested appearance of the tonsil suggests an infection in the follicles themselves which has cut off communication with the surface. Such conditions may be associated with permanent injection of the buccal surface of the anterior faucial pillar and sometimes with enlargement of the lymph node just behind the angle of the jaw. On neither clinical nor bacteriologic examination of the tonsils before operation can it be decided that a tonsil is a focus of general infection, even if hemolytic streptococci are obtained in pure culture from the tonsils. The decision in regard to focal infection can be made only after the tonsils have been removed and the patient has returned to good health The return of good health is presumptive evidence that the tonsils were a focus of infection.

Kaiser did not observe immediate benefits after the removal of tonsils in children, but over a 10-year period following the removal of tonsils there were a reduction in the incidence of sore throat, and a decrease in the susceptibility to scarlet fever, diphtheria, cervical adenitis, first attacks of rheumatic fever, and otitis media.

Symptoms. In some children and adults there are very definite symptoms from enlarged tonsils The tone of the voice frequently is thick, and there is a ring or resonance about it which can be distinguished from that caused by nasal or laryngeal obstruction Articulation may be indistinct. If the patient makes a complaint, it may be of a sensation of fullness in the throat. Often there is a recurring eustachian catarrh with each bad cold The cervical lymph nodes are chronically enlarged. There may be a foul breath or a disagreeable taste in the mouth

Hypertrophied tonsils which should be surgically removed are accompanied by a history of frequent attacks of tonsillar inflammation or of peritonsillar abscess. There is interference with respiration by day or by night, and occasionally an alteration of the voice is noticeable.

The prognosis after the removal of the tonsils in those who have had repeated attacks of eustachian catarrh or inflammatory disease of the middle ear is guarded. The removal of the tonsils in the presence of these diseases should be advised strictly on its own merits for treatment of the local condition which may be demonstrated. No doubt at times general systemic benefits will be obtained from the removal of the tonsils, but these benefits cannot be predicted.

Singers, or those who wish to be singers, often want to know if removal of the tonsils will interfere with singing In those who are already singers there is certainly a risk that the instinctive control of the muscles used in singing may be temporarily lost to such a degree as to impart a peculiar tone to the voice which previously was prized However, in those who are already singers, after tonsillectomy a renewed study and practice will often result in a stronger and better voice, if not one of precisely the same tone

Patients who are only beginning the study of singing can safely be advised to [illegible]

to relearn the complete use of the muscles which have been liberated by removal of the tonsils.

beyond the fifth year, negative reactions increase, and in adult persons the same ratio of negative to positive skin tests prevails as in newborn children; that is, 9 out of 10 are negative.

SYMPTOMS. The period of incubation of diphtheria varies from 2 to 10 days, but is usually 2 or 3 days The onset is with fever, temperature 102 to 104 F (38.9 to 40 C), chilliness, headache and pain in the back and limbs

There is nothing distinctive in the initial symptoms, which vary according to the site of the specific inflammation. Generally there are sore throat and dysphagia. A croupy cough, hoarseness or aphonia, and above all, evidences of progressive laryngeal stenosis constitute a dangerous involvement of the larynx If there is an extension of the membrane into the trachea and the bronchial tubes, the breathing may become stridulous, and dyspnea and cyanosis are manifest

Often the symptoms of diphtheria are mild, with slight fever and little if any prostration In diphtheria gravis there are extensive and intense local changes, the prostration is extreme, the temperature is subnormal, the face is ashy, the pulse rapid and feeble. Subcutaneous ecchymoses appear

Extraneous infections and symptoms of diphtheria are common A cutaneous wound may become infected and a pseudomembrane may form at the point of lodgment of the germs Diphtheria of the conjunctiva may occur primarily, or by extension from the nose; of the external ear, from the discharge of a diphtherial otitis media; of the mouth and lips, by extension; of wounds, ulcers, and the genitals, by direct infection from contaminated hands, instruments, or dressings. Diphtheritic paralysis may be a serious complication (see Chapter 15).

EXAMINATION. There are swollen and tender cervical lymph nodes. There may be apparent stiffness of the cervical tissues

The tonsils are swollen and covered with grayish or yellowish white membrane, which is usually adherent and leaves a bleeding surface when forcibly stripped off. By the second or third day the membrane extends to the faucial pillars, perhaps also to the uvula and the posterior pharyngeal wall Under favorable conditions the symptoms subside and the throat becomes clear of membrane by the tenth day

If the inflammation extends to the nose, there is an offensive, often bloody, discharge from the nostrils, or epistaxis. In certain instances, there may be thick membranes in the nose containing diphtheria bacilli, but constitutional symptoms are absent and the disease is relatively harmless (fibrinous rhinitis) On extension of the infection to the tonsils the membrane may appear punctate and be confined to the tonsils, simulating an ordinary follicular tonsillitis, or there may be a soft nonmembranous exudate on the tonsils alone; or the disease may be so extremely mild that membrane or exudate does not appear, the throat presenting only the redness of an ordinary catarrhal inflammation

On extension of the disease to the larynx the supraclavicular, episternal, intercostal and epigastric spaces are deeply retracted with inspiration and bulge with expiration. Shreds of membrane may be coughed up If the stenosis is not relieved, the child passes into a semicomatose state and death ensues after a few hours to several days.

DIAGNOSIS. The diagnosis is established by positive cultures from the throat for the Klebs-Löffler bacillus in the presence of a membrane and other variable symptoms and signs as enumerated.

Chronic Tonsillitis; Chronic Enlargement of the Tonsils. The cause of lymphoid hypertrophy of the tonsils is not known. Generally the tonsils begin to enlarge at the age of 3 or 4 years They begin to shrink at about the age of 12 years, and tend to diminish or to become much smaller at about the age of puberty. Sex does not seem to have any influence on occurrence of tonsillar hypertrophy. In a hypertrophied or an enlarged tonsil there is an increase in the normal structures. In some the crypts are more distinctive and contain a variable amount of mucus,

unilateral enlargement or a deep, spreading ulceration on an enlarged tonsil, from which an offensive, sanguineous discharge issues, is in all probability cancerous.

Most malignant tumors of the tonsils are anaplastic epidermoid carcinomas arising in the mucous membrane covering the tonsil or lining a crypt Lymphosarcoma of the tonsils arises less frequently. The malignant lesions arising within the tonsil itself are usually more rapidly growing and much more radiosensitive than are carcinomas arising on neighboring mucous membranes and invading the tonsil secondarily. The diagnosis is made by biopsy study of tissue secured from the lesion or of the removed tonsil.

THE NOSE

The nose is long, short, flat, small or large. The contour of the nose viewed in profile is formed by an upper portion of bone, the bridge of the nose; a middle, of cartilage, and a lower, or tip, also of cartilage. The bridge of the nose slopes downward and forward, and where it joins the upper lateral cartilage, the line changes and slopes more sharply downward until the tip is reached Here the lower lateral cartilages bulge forward, forming a rounded and often a projecting tip

The skin over the tip and alae is thick and adherent to the cartilages. It possesses a comparatively scanty blood supply, hence its liability to suffer from exposure to cold, and it is a favorable site for ulcerations (lupus) and superficial epithelioma (rodent ulcer). Sebaceous and sweat glands are abundant. The skin is often pockmarked from acne. Stiff hairs guard the inside of the nostrils. The follicles of these hairs are often the seat of small furuncles or boils which are extremely painful, owing to the tension caused by the congestion and the swelling, which is restricted by the tissues being so firmly bound to the cartilages beneath.

Anomalies and Deformities. A nose with stenosed nares or an incomplete septum represents a persistence of the normal fetal anatomy A failure of the region between the nasal sacs to consolidate into a septum permits apical bifurcation or duplication of the nose. A rare anomaly of the nose is cyclopia. a tubular proboscis attached above the single median eye

The nose may be long and its midportion bowed forward with the tip turned down toward the upper lip Such a deformity is of developmental origin, often hereditary Contrasted with the nose of this shape is the short nose with the external surface curved inward toward the face, with the nares large and pointing outwardly and very obvious. The shape of this nose too is of developmental origin, often hereditary A comparable deformity, less the forward opening of the nares, is produced by surgical injuries and traumatic fractures of the bony part of the nasal septum This deformity may be, but is rarely, due to syphilis The nasal septum may become ulcerated and perforated and deformed so severely from the inhalation of toxic gases that the external contour will become deformed

In cretinism and myxedema the nose becomes coarse and broad It is broadened or distorted and displaced by growing tumors in the nasal cavities or in the adjacent facial bones.

Rhinophyma and Redness. Rhinophyma is a chronic hypertrophy of the skin of the nose and edges of the alae nasi. The cause is rosacea, and the condition occurs in middle-aged or aging men

Chronic redness of the nose is due to dilated capillaries and, if not normal, it usually results from sunburn, windburn or rosacea It is rarely due to chronic alcoholism

Small dilated blood vessels appearing over the tip and alae of the nose occur in different disease conditions, especially cirrhosis of the liver In this disease the small nevi, vascular spiders, formed by small dilated vessels, which are known to be minute arteries, are a common although not a diagnostic manifestation The

Peritonsillar Abscess (Quinsy or Cynanche). Inflammation and formation of pus in the tissues adjoining, but outside, the tonsil is known as quinsy. The condition is a peritonsillar abscess

The illness begins with fever and a chill, which is followed by an acute pain behind the angle of the jaw and extending up to the ear and down the neck on the same side as the abscess. Swallowing is so painful that often the patient will allow the saliva to run from the open mouth rather than endure the pain that attends an attempt to swallow or to expectorate. Accumulation of secretions in the pharynx adds a rattling character to the heavy thick tone of the patient's voice The neck is held stiffly and the head is forward and inclined to the affected side. The tongue is protruded with the greatest of difficulty Thirst often is intense. Taste is lost early in the disease and the sense of smell is diminished. The patient's breath becomes offensive, and the patient is pale and anxious and soon is very much exhausted The temperature in the early stages of the disease may reach as high as 105 F (40 6 C) The abscess often ruptures through the tonsil itself into the superior tonsillar fossa or through the anterior pillar and soft palate. With rupture of the abscess, after 5 to 10 days, the general symptoms cease at once and the local discomfort abates rapidly. Some days or weeks are required before the patient returns to normal health

On examination there is tenderness over the whole side of the neck. The lymph nodes at the angle of the jaw and along the sternocleidomastoid muscle are swollen and tender. Diffuse tenderness also may be present in the submaxillary, parotid or occipital nodes. The isthmus of the fossae is considerably narrowed by the bulging of the anterior pillar and neighboring portion of the soft palate The swelling may be such that the tonsil itself, which may not actually be swollen at all, may not be visualized The surface of the tonsil and the abscess often is coated with a deposit of mucopus resembling a false membrane, which is readily detached. A valuable sign in the diagnosis of a peritonsillar abscess is a loss of mobility of the soft palate on the affected side The tip of the uvula tends to point toward the tonsil around which there is an abscess Edema of the larynx is rare but if it occurs, it may be of very serious import

A patient usually recovers from a peritonsillar abscess, but the spontaneous bursting of a large abscess which floods the trachea with pus while the patient is asleep may cause death. Hemorrhage from a peritonsillar abscess may occur as a primary or as a secondary event, with or without surgical drainage of the abscess

Among the possible complications of quinsy are septicemia, bronchopneumonia, thrombophlebitis, pyemia, cellulitis of the neck, seropurulent pleurisy, meningitis, suffocation from pressure, secondary edema of the glottis and acute edema of the lungs

Tuberculosis. In the adult, tonsillar tuberculosis is of slight importance because, on the whole, it is only a secondary localization in an advanced pulmonary tuberculosis In children, it presents as either a secondary localization to pulmonary tuberculosis or a form of pharyngeal infection Tonsillar tuberculosis may be latent and thus is detected only by histologic examination Tuberculosis of the cervical lymph nodes and tonsillar tuberculosis are frequently associated. Every patient whose tonsils disclose tuberculosis should be kept under observation until it is clear that pulmonary tuberculosis is not present Tonsillectomy involves no great risk in the presence of tonsillar tuberculosis if the pharynx too is not deeply involved.

Tumors. There is a general belief that simple tumors of the tonsils are practically nonexistent. This statement is generally true, however, papillomas, adenomas, fibromas, angiomas, dermoid tumors and, occasionally, lipomas are all seen in this region. In addition to these tumors occasional keratomas, mixed tumors and retention cysts and hardened areas of scar tissue are seen.

Malignant tumors of the tonsils occur after 50 years of age In an elderly person

Discharges From the Nose. Nasal discharges may be watery, mucous, mucopurulent or purulent; or bloody or composed of blood alone, according to the nature and seat of the causal condition.

A *watery discharge* marks the beginning of acute coryza, vasomotor rhinitis, hay fever, the catarrhal form of epidemic influenza, pertussis, measles, and typhus and other fevers. In a few days a watery discharge often grows thick and mucopurulent. Watery fluid may flow from one nostril during an attack of trigeminal neuralgia. An occasional watery discharge, with persistent obstruction of one or both nostrils, may be due to nasal polyps. A recurring flow of pus from one nostril, particularly if brought on by lying on or leaning over toward the side opposite to that which is discharging, is probably due to an antral abscess, and the probability is increased if bad teeth are present. In children the possibility of a foreign body should not be overlooked in all instances of nasal discharges not easily accounted for. Finally, irritating gases or powders will produce a smart watery flow

Bloody discharge may be significant of an impacted foreign body. Coming on in the course of pharyngeal diphtheria and irritating the parts with which it comes in contact, such a discharge may indicate nasal infection before membrane can be discovered in the nasal cavities. An offensive discharge from both nostrils, which may be accompanied with greenish gray crusts, is symptomatic of atrophic rhinitis, or may be due to syphilis, caries or necrosis of the bones. It may be a sequel of scarlatina. The patient is usually unconscious of the fetid odor. Cancer or lupus affecting the nasal chambers or encroaching on them may also be responsible for a discharge possessing an unpleasant smell

Cerebrospinal Rhinorrhea. This is a rare condition caused usually by operative or accidental trauma, especially fractures at the base of the skull. It may begin without any known cause. In instances of increased intracranial pressure spinal fluid may escape to the nose and in the presence of the accompanying disturbances of the sensorium and the recumbent position of the patient it drains back into the throat and causes gurgling, coughing and choking Ordinarily there is a constant drip of the clear fluid from the nose.

The diagnosis depends on the presence of a clear fluid from the nose which does not contain mucin or albumin but contains sugar as evidenced by the reduction of copper in a copper-containing solution such as Fehling's solution

Epistaxis. A discharge of blood from the nose may be a result of either local or general causes It is usually a capillary oozing, and on inspection the bleeding area is seen to be congested, ecchymotic or superficially ulcerated A common site of the bleeding spot is on the cartilaginous septum Less frequently it arises from the posterior end of the middle turbinated body or, in children with adenoids, from the vault of the pharynx or at times from the accessory sinuses Specular inspection under a good light, clots having [illegible]
termine the exact location of the [illegible]
the blood may run into the ph [illegible]
vomited or, if clinging to the pharynx, be hawked up, thus simulating hematemesis or hemoptysis Nosebleed from local causes is usually unilateral, but if the nosebleed is due to blood changes or general diseases, it is likely to take place from both sides.

Ordinarily epistaxis is not sufficiently severe to produce constitutional symptoms, but after trauma or operations on the nose or in cases of hemophilia it may be profuse or continue long enough to threaten life seriously, although an actual fatal result is extremely rare

Nasal Causes of Epistaxis Aside from traumatic causes, caries or necrosis of the nasal bones, ulceration from a foreign body or other causes, polyp, new growths, varicosities or chronic nasal catarrh may be responsible for epistaxis. Hypertension with accompanying arteriosclerosis and alcoholism may render the vessels liable to rupture. The latter causes rarely produce nosebleed.

General Causes of Epistaxis People of full habit may have a rather frequently recurring nosebleed Delicate children suffer from it, especially at puberty and after

vascular nature of the spiders may be demonstrated by pressing the point of a pencil on one of the arteries where it is seen to emerge from the deep layers of the skin. During application of pressure in this manner the vessel is obliterated.

Acute redness of the nose, with pain and swelling, especially of one ala, may be the result of a small pustule or boil.

In a young person a superficial ulceration of the wing of the nose, usually painless, beginning as a reddish papule, spreading in various directions, and healing in one portion while breaking down in another, is probably a tuberculous ulcer. In an elderly patient a small, hard, scabbing ulcer, somewhat painful, gradually extending, and perhaps attended with involvement of lymph nodes, is an epithelioma.

Collapse of the Alae Nasi. The alae nasi collapse when an unnatural weakness of the lateral aspects of the lateral walls of the distal part of the nose is present. This condition is a developmental defect, often inheritable. The nose is long and narrow in contour. The collapse of the nares occurs during inspiration and thus produces varying degrees of nasal obstruction.

Atresia of the Alae Nasi. In congenital atresia of the alae nasi there is a failure of perforation or absorption of epithelium of the developing nose. Acquired atresia of the alae may be engendered by healing tuberculosis, syphilis or trauma.

Acting Nares; Regurgitation of Fluids. In some sensitive and neurotic individuals the nostrils dilate with each inspiration, especially under mental excitement. Aside from this, acting nares indicate dyspnea or anoxia of various origins, and among other conditions are very noticeable in emphysema, asthma, pneumonia, obstructive diseases of the larynx and the broken compensation of cardiac valvular lesions.

If on the patient's attempting to swallow fluids a portion escapes through the nostrils, one of three conditions is usually present: cleft palate, paralysis of the soft palate (diphtheritic) or bulbar paralysis.

Pain in or Around the Nose. Burning or smarting sensations usually attend coryza or other acute catarrhal inflammation. If great pain in the nasal chambers is present, it may be a symptom of an ulcerating lesion or of an impacted foreign body. Severe pain just above the root of the nose, accompanied with fever, may be due to inflammation of the frontal sinuses. Pain in the nose and cheek is due to inflammation of the antrum. Pain referred to the nasal cavities and ears is due to inflammation of the eustachian tubes. Inflammation of the eustachian tubes is often associated with diseases of the nasal passages. A sensation of dryness is a common complaint in the early and late stages of coryza and is a persistent and annoying symptom of atrophic rhinitis.

Inflammation and engorgement of the turbinates, ostia, nasofrontal ducts and superior nasal spaces are responsible for most of the pain from most of the paranasal structures. The pain emanating from the nasal and the paranasal structures is relieved by shrinkage of the nasal structures.

Diseases of the superior nasal structures cause headaches, primarily in the front and top of the head and between the eyes. Diseases of the middle and inferior nasal structures cause headaches over the zygomas and temples and in the teeth and jaws.

When the turbinates are painful, the pain is augmented by shaking the head and by lowering it between the knees. The presence of purulent secretion in the sinuses is not necessarily the basis for headache.

Local vasomotor changes in the erectile tissues of the nose occur as accompaniments of stress, exhaustion, sexual excitement, and various emotional states which may or may not be associated with symptoms. If there should be inflammation of the nose, these changes enter awareness and thus cause symptoms. Furthermore, congestion of the nasal mucous membranes may occur without inflammation as an accompaniment of anxiety or resentment.

To test the function of the olfactory nerve, nonirritating substances must be used, as pungent vapors affect mainly the trigeminal nerve Suitable odorous agents are musk, oil of cloves and peppermint in convenient containers It should be remembered that the perception of any single odor is lost in 3 or 4 minutes but is regained after 1 minute of rest. It is essential that the odorous material should enter the nostrils as a vapor or in a state of fine division, the act of smelling is usually assisted by sniffing, which is a modified inspiration. It is also necessary that the mucous membrane should be moist in order for the odorous particles to enter into solution on its surface.

The clinical symptoms relating to the sense of smell are *anosmia*, loss of the sense of smell; *hyperosmia*, increased sensitiveness of the sense of smell, and *parosmia*, subjective perversion of the olfactory sense.

Anosmia. The loss of the sense of smell, in the majority of instances, is due to local disease of the nasal mucous membrane, namely, chronic rhinitis, particularly the atrophic variety, and polyps or other new growths. The inhalation of irritating vapors or extremely foul odors may temporarily or permanently abolish the sense of smell. Paralysis of the trigeminal nerve will impair the olfactory power of the affected side. Loss of the power of smell may be a symptom, purely neurotic, of neurasthenia and hysteria.

Frequently the sense of smell is abolished because of injury or lesion of the olfactory bulb or tract Falls or blows on the head, affecting the nerve in its course, may produce as the only symptom of injury a persistent anosmia. Caries of the bones supporting the tract or bulb, and basal meningitis or tumors involving the nerve, may be instrumental in causing olfactory anesthesia. Possibly from atrophy of the nerves, anosmia may be one of the symptoms of locomotor ataxia. Anosmia is sometimes congenital, resulting from imperfect development of the olfactory nerve tissue Partial anosmia may be due to a lesion of the uncinate gyrus or to disease of one hemisphere

Hyperosmia. Hyperosmia or abnormal sensitiveness of the sense of smell is, in its slighter degrees, not an uncommon symptom in neurotic individuals More rarely the sensitiveness is extreme and is symptomatic of hysteria and neurasthenia

Parosmia. Olfactory sensations without a physical basis, the apparent odors usually being unpleasant or offensive (*kakosmia*), are not infrequent as hallucinations in the psychoses A bad odor may constitute the premonitory aura of epilepsy Subjective kakosmia has been associated in a limited number of cases with tumor of the hippocampus

Olfactory Acuity and Appetite. Elsberg and Levy introduced a simple method of measuring olfactory acuity Measured volumes of odorous air were injected into both nostrils The smallest volume which produced a sensation of odor was taken as a measure of the olfactory threshold Using bottles containing constant amounts of ground coffee as sources of odorous air, Goetzel and associates measured the diurnal variations in olfactory acuity They found that on days when lunch was omitted the olfactory acuity increased gradually from the early morning until the end of the work day. This increased olfactory sense was accompanied with a parallel increase in the hunger sense This basic pattern was modified on days when lunch was eaten during the midday rest period As a result of the lunch the olfactory acuity fell precipitously to a relative olfactory insensitiveness as the sensation of hunger was converted into one of satiety This dullness of the olfactory sense persisted for about 3 hours, when a rapid increase in olfactory acuity set in, accompanied with a return of the hunger sense

Postnasal Drip. A postnasal drip is of importance mainly from the local discomfort and anxiety that it gives the patient who is thus affected

Postnasal drip is produced by many and varied etiologic agents It is often associated with the various forms of rhinitis, lymphoid hyperplasia of the pharynx, and enlarged adenoids and lingual tonsils It is caused by irritations and by dust on the nasal mucous membranes, as well as by excessive tobacco smoking and medications in the way of nasal sprays and nasal washes containing drying agents. The

exertion under a hot sun. It is a common complaint of mountain climbers at considerable altitudes, and inhalation of very hot or very cold air may induce it. In suppressed menstruation it may be vicarious The chronic anemias are frequently attended by epistaxis It is a symptom of leukemia, purpura haemorrhagica and scurvy and is the most ordinary form of hemorrhage in hemophilia. Less commonly it may be the result of cardiac hypertrophy and valvular disease, enlarged bronchial lymph nodes, pleurisy with large effusion, emphysema and the strain of pertussis.

Epistaxis is a symptom of diagnostic value in the prodromal stage of typhoid fever, and is an occasional event in other infections such as erysipelas, pyemias, malarial fever, viral, rickettsial and leptospiral infections

[illegible] Telangiectasia (Osler's Disease). This telangiec- [illegible] by the presence of multiple acquired angiomas of varying [illegible] with a tendency to bleed spontaneously or from slight trauma The disease has been traced through six generations in one family In about 20 per cent of the cases there is no family history of a simi- [illegible]

[illegible] ectasia of preexisting vascular channels [illegible] endothelial [illegible] taxis

[illegible] develop in the [illegible] treatment, the lesions have a universal [illegible] a tendency to disappear spontaneously while new angiomas appear

The first symptom is abnormally profuse epistaxis beginning at about puberty. This is followed by the development of multiple telangiectasias of the skin and mucous mebranes from the age of 25 to 35 years All symptoms tend to reach their greatest severity from 30 to 39 years of age

Fissure on the Nasal Vestibule. A fissure on the nasal vestibule is a common complication or sequence of a nasal discharge from any cause. It often happens during the course of coryza and hay fever. A less common cause is syphilis The fissure is painful and the tip of the nose is tender The skin about the fissure is reddened

Sneezing. This is a spasmodic expiration, caused usually by direct, rarely by reflex, irritation of the sensory nerves of the nose, which occurs as an early symptom of coryza, measles, pertussis, asthma and hay fever Small doses of the iodides in susceptible individuals, and large doses in many others, will induce it, as well as the inhalation of various irritants such as dust, pepper and snuff Prolonged paroxysms of sneezing have been asserted to be of hysterical origin Syringing or manipulation of the external auditory canal will sometimes provoke a reflex sneeze A common cause of sneezing is a hypersensitive lining of the nose such as is present in vasomotor rhinitis

Picking at the Nose. Picking at the nose with the finger by a child was formerly considered to be a sign that the child had intestinal worms. It has been said that picking at the nose is common in those who have brain tumors However, picking at the nose is an expression of nervous tension and shyness Nervous or shy persons may have in due time either worms or brain tumors but picking at the nose is a sign of neither intestinal parasites nor brain tumors.

The Sense of Smell. The olfactory bulbs and their associated parts are in reality portions of the brain. The peripheral nerves arising from the bulbs are distributed to the mucous membrane of the upper portion of the nasal septum, the superior and middle turbinates, and the proximal part of the nasal septum. These distributions of the olfactory nerve can be identified by their yellowish brown color The free end of an olfactory cell is rodlike and reaches the surface of the epithelium, where it divides into small projecting olfactory hairs of microscopic dimensions The center for the sense of smell is said to be in the uncinate convolution.

To test the function of the olfactory nerve, nonirritating substances must be used, as pungent vapors affect mainly the trigeminal nerve. Suitable odorous agents are musk, oil of cloves and peppermint in convenient containers. It should be remembered that the perception of any single odor is lost in 3 or 4 minutes but is regained after 1 minute of rest. It is essential that the odorous material should enter the nostrils as a vapor or in a state of fine division; the act of smelling is usually assisted by sniffing, which is a modified inspiration. It is also necessary that the mucous membrane should be moist in order for the odorous particles to enter into solution on its surface.

The clinical symptoms relating to the sense of smell are *anosmia*, loss of the sense of smell, *hyperosmia*, increased sensitiveness of the sense of smell; and *parosmia*, subjective perversion of the olfactory sense.

Anosmia. The loss of the sense of smell, in the majority of instances, is due to local disease of the nasal mucous membrane, namely, chronic rhinitis, particularly the atrophic variety, and polyps or other new growths. The inhalation of irritating vapors or extremely foul odors may temporarily or permanently abolish the sense of smell. Paralysis of the trigeminal nerve will impair the olfactory power of the affected side. Loss of the power of smell may be a symptom, purely neurotic, of neurasthenia and hysteria.

Frequently the sense of smell is abolished because of injury or lesion of the olfactory bulb or tract. Falls or blows on the head, affecting the nerve in its course, may produce as the only symptom of injury a persistent anosmia. Caries of the bones supporting the tract or bulb, and basal meningitis or tumors involving the nerve, may be instrumental in causing olfactory anesthesia. Possibly from atrophy of the nerves, anosmia may be one of the symptoms of locomotor ataxia. Anosmia is sometimes congenital, resulting from imperfect development of the olfactory nerve tissue. Partial anosmia may be due to a lesion of the uncinate gyrus or to disease of one hemisphere.

Hyperosmia. Hyperosmia or abnormal sensitiveness of the sense of smell is, in its slighter degrees, not an uncommon symptom in neurotic individuals. More rarely the sensitiveness is extreme and is symptomatic of hysteria and neurasthenia.

Parosmia. Olfactory sensations without a physical basis, the apparent odors usually being unpleasant or offensive (*kakosmia*), are not infrequent as hallucinations in the psychoses. A bad odor may constitute the premonitory aura of epilepsy. Subjective kakosmia has been associated in a limited number of cases with tumor of the hippocampus.

Olfactory Acuity and Appetite. Elsberg and Levy introduced a simple method of measuring olfactory acuity. Measured volumes of odorous air were injected into both nostrils. The smallest volume which produced a sensation of odor was taken as a measure of the olfactory threshold. Using bottles containing constant amounts of ground coffee as sources of odorous air, Goetzel and associates measured the diurnal variations in olfactory acuity. They found that on days when lunch was omitted the olfactory acuity increased gradually from the early morning until the end of the work day. This increased olfactory sense was accompanied with a parallel increase in the hunger sense. This basic pattern was modified on days when lunch was eaten during the midday rest period. As a result of the lunch the olfactory acuity fell precipitously to a relative olfactory insensitiveness as the sensation of hunger was converted into one of satiety. This dullness of the olfactory sense persisted for about 3 hours, when a rapid increase in olfactory acuity set in, accompanied with a return of the hunger sense.

Postnasal Drip. A postnasal drip is of importance mainly from the local discomfort and anxiety that it gives the patient who is thus affected.

Postnasal drip is produced by many and varied etiologic agents. It is often associated with the various forms of rhinitis, lymphoid hyperplasia of the pharynx, and enlarged adenoids and lingual tonsils. It is caused by irritations and by dust on the nasal mucous membranes, as well as by excessive tobacco smoking and medications in the way of nasal sprays and nasal washes containing drying agents. The

complaint is frequent hawking and clearing the throat, especially marked on arising in the morning and during or soon after meals The patient often interprets the symptoms as being due to sinusitis. Cough and hoarseness may be the chief complaint when laryngitis is present Often there are sensations of tightness, of dryness and fullness of the throat There may be difficulty in nasal breathing Some impairment of hearing may result from obstructions of the eustachian tubes Often in the morning, in attempts to clear the throat and the back of the nose of the tenacious secretion, vomiting may ensue. Generally speaking, a postnasal drip does not produce disease of the lungs or of the stomach, swallowing of the material is harmless and normal

Rhinitis. *Acute rhinitis* is characterized successively by a feeling of dryness in the nose, nasal obstruction, anosmia, and then a watery, irritating nasal discharge. Accompanying these manifestations often are sneezing, lacrimation, headache, fullness and discomfort in the ears, and fever.

Acute rhinitis *accompanies many and varied conditions. It is often the beginning* of an infection of the upper part of the respiratory passages.

Chronic Rhinitis. Chronic rhinitis *often follows an acute attack of rhinitis, or it* may result from a succession of mild attacks of coryza, or may be left after measles, scarlet fever or other specific infection. This condition is not contagious. It is frequently met with in those exposed to dusty occupations. The commonest symptom of chronic rhinitis is nasal obstruction, which seldom is complete It is generally intermittent, being worse after meals, in certain conditions of weather and at night During the day it may be negligible, but at night the nostrils become so obstructed that mouth breathing with all its discomforts is present On examination there is an engorgement of the vessels with chronic inflammatory changes in the mucosa

Hypertrophic Rhinitis. The complaint in hypertrophic rhinitis is of abundant, sometimes thick, mucopurulent discharge, occasionally stained with blood if much *force has been used in expelling it There is nasal obstruction, worse at night than* by day, and influenced by gravity so that the nasal chamber toward the pillow is most obstructed The obstruction may be sufficient to induce mouth breathing. The sense of smell is diminished, hence much of the perception often attributed to taste is lost The voice loses its nasal resonance. Discomfort or actual pain may be caused by pressure of a congested turbinal body on the septum.

Atrophic Rhinitis. Atrophic rhinitis is a chronic rhinitis of unknown origin and occasionally occurs in several members of a family The affection tends to disappear after middle life The condition is much less common in men than in women. It is characterized by atrophic changes in the nasal mucosa and *turbinated bones*, abnormal patency of the nasal fossa and a mucopurulent discharge with foul odor. The sufferer, however, is rarely aware of the odor, for as a rule the disease causes [illegible] the separa-

[illegible] eign bodies,

rhinolith, empyema, lupus or suppurating adenoids

Vasomotor Rhinitis (*Spasmodic Rhinorrhea*). Vasomotor rhinitis may be defined as an intermittent engorgement of the nasal mucous membrane associated with a free discharge of dilute mucus, frequently with paroxysmal *sneezing and suffusion* of the eyes. Often there are present a hypersensitivity of the nasal mucosa and some external irritation acting on the nasal mucosa. The psychoneurotic element is an important causative factor. Examination of the mucous membrane during an attack shows passive engorgement.

The attacks come with great suddenness, often in the early morning, and commence with a feeling of tickling or dryness in the nose. Perhaps the same sensation in the *conjunctivae* and a sudden attack of violent sneezing usher in a discharge of profuse watery mucus from the nostril. The sneezing may be so violent and uncon-

trollable as to cause ecchymosis of the conjunctivae. Often, as soon as the mucous membrane has been wetted by secretions, the attack ceases

Nasal Leprosy. Leprosy of the nose is manifested by chronic nasal obstruction, bloody nasal discharge and marked crusting. As time passes, there is destruction of parts of the nose with perforation of the nasal septum and maximal external nasal deformities.

The diagnosis is established by the presence of other symptoms of leprosy and by the demonstration of the bacilli in the nasal discharges Often the diagnosis of leprosy can be established by the administration of 10 drops of a saturated solution of potassium iodide in water to increase the nasal secretions. At the height of the secretion, about 2 hours after administration of the drug, the nasal septum and the nasopharynx are swabbed with a cotton applicator and the material is fixed on a glass slide by heat, stained with carbolfuchsin, and counterstained with methylene blue. *Mycobacterium leprae* is acid fast.

Screwworm Infestation (Cochliomyia americana) of the Nose. The common site of screwworm infestation in man is the nose, but infestation of nasal sinuses, pharynx, throat, mouth, ear, orbit, eyeball and open wounds may also take place. The chief predisposing factor in rhinal myiasis is a pre-existing pathologic condition of the nose. A cut, scratch or abrasion of the skin is necessary to attract the female screwworm fly. Sleeping in the open invites infestation The eggs hatch out 24 hours after being deposited in a favorable environment The symptoms include partial obstruction to breathing on the affected side and a feeling of discomfort accompanied with a strange sensation at the root of the nose that becomes an intense pain. Sneezing may occur at the onset, and severe headache may persist. A serosanguineous nasal discharge of offensive odor accompanies these symptoms. With the onset of this discharge, the patient may clear his throat repeatedly, expectorate frequently and cough up a purulent material that may contain living or dead larvae. Removal of the larvae is accomplished mechanically and by the use of drugs Chloroform applied locally and as a vapor is the drug of choice Although screwworm infestation occurs chiefly in the Southern states, cases have been observed as far north as Missouri and Illinois

Diseases of the Nasal Septum. The septum in most noses is somewhat irregular and rarely is placed evenly between the nares.

Ulcers. A commonly occurring ulcer of the nasal septum develops as the result of habitual picking of the nose with the index finger, a habit caused by nervous tension. The inception is manifested as a septal erosion from repeated trauma The urge to do more picking of the nose is made stronger by the irritation and discomfort The septum may be deeply injured and the mucosa may be denuded

Rare causes for ulcers of the nasal septum are syphilis and trauma from irritating chemicals and particulate matter such as organic and inorganic particles or dusts

Once the ulcer is established, there ensue nasal irritation and epistaxis If syphilis is the cause, there is a foul nasal discharge with destruction of the septum

The ulcer is identified by endoscopic examination

Deformities. The deformities are classified as spurs, deviations, and combinations of spurs and deviations. If of a sufficient degree, these deformities originate the complaint of nasal obstruction and inability to clear one or both nostrils Any of the sequelae of mouth breathing, however, may be due to aberrations of the nasal septum.

A spur is found to consist of a crust, a spina or a thickening It is chiefly cartilage, but it is often present at the junction of cartilage and bone, both of which enter into its formation. Deviations of the nasal septum are almost always more pronounced in the cartilaginous portion of the septum than in the bony portion.

complaint is frequent hawking and clearing the throat, especially marked on arising in the morning and during or soon after meals. The patient often interprets the symptoms as being due to sinusitis. Cough and hoarseness may be the chief complaint when laryngitis is present. Often there are sensations of tightness, of dryness and fullness of the throat. There may be difficulty in nasal breathing. Some impairment of hearing may result from obstructions of the eustachian tubes. Often in the morning, in attempts to clear the throat and the back of the nose of the tenacious secretion, vomiting may ensue Generally speaking, a postnasal drip does not produce disease of the lungs or of the stomach, swallowing of the material is harmless and normal.

Rhinitis. *Acute rhinitis* is characterized successively by a feeling of dryness in the nose, nasal obstruction, anosmia, and then a watery, irritating nasal discharge. Accompanying these manifestations often are sneezing, lacrimation, headache, fullness and discomfort in the ears, and fever

Acute rhinitis accompanies many and varied conditions It is often the beginning of an infection of the upper part of the respiratory passages

Chronic Rhinitis. Chronic rhinitis often follows an acute attack of rhinitis, or it may result from a succession of mild attacks of coryza, or may be left after measles, scarlet fever or other specific infection This condition is not contagious It is frequently met with in those exposed to dusty occupations. The commonest symptom of chronic rhinitis is nasal obstruction, which seldom is complete It is generally intermittent, being worse after meals, in certain conditions of weather and at night. *During the day it may be negligible, but at night the nostrils become so obstructed* that mouth breathing with all its discomforts is present. On examination there is an engorgement of the vessels with chronic inflammatory changes in the mucosa.

Hypertrophic Rhinitis. The complaint in hypertrophic rhinitis is of abundant, sometimes thick, mucopurulent discharge, occasionally stained with blood if much force has been used in expelling it There is nasal obstruction, worse at night than by day, and influenced by gravity so that the *nasal chamber toward the pillow is* most obstructed *The obstruction may be sufficient to induce mouth breathing.* The *sense of smell is diminished, hence much of the perception often attributed to taste* is lost The voice loses its nasal resonance Discomfort or actual pain may be caused by pressure of a congested turbinal body on the septum.

Atrophic Rhinitis. Atrophic rhinitis is a chronic rhinitis of unknown origin and occasionally occurs in several members of a family. The affection tends to disappear after middle life *The condition is much less common in men than in women.* It is characterized by atrophic changes in the nasal mucosa and turbinated bones, abnormal patency of the nasal fossa and a mucopurulent discharge with foul odor. The sufferer, however, is rarely aware of the odor, for as a rule the disease causes a loss of the sense of smell The discharge tends to dry and to crust and the separation of the crusts from the nose may cause slight bleeding

Atrophic rhinitis symptomatically may resemble the symptoms of foreign bodies, rhinolith, empyema, lupus or suppurating adenoids

Vasomotor Rhinitis (*Spasmodic Rhinorrhea*) Vasomotor rhinitis may be defined as an intermittent engorgement of the nasal mucous membrane associated with a free discharge of dilute mucus, frequently with paroxysmal sneezing and suffusion of the eyes. Often there are present a hypersensitivity of the nasal mucosa and some external irritation acting on the nasal mucosa The psychoneurotic element is an important causative factor. Examination of the mucous membrane during an attack shows passive engorgement

[illegible] ...great suddenness, often in the early morning, and com- [illegible] or dryness in the nose. Perhaps the same sensation [illegible] ...n attack of violent sneezing usher in a discharge of profuse watery mucus from the nostril The sneezing may be so violent and uncon-

of the nose is determined by roentgenologic examination. The diagnosis of malignant disease is established by biopsy.

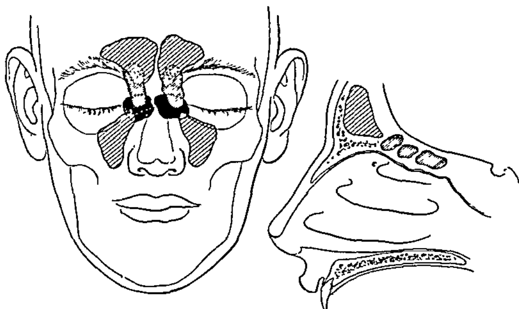

Fig 4-2 Accessory nasal sinuses

The Accessory Sinuses. The accessory sinuses or air cells of the nose are the frontal, ethmoidal, sphenoidal and maxillary (Fig. 4-2). They vary in size and form in different individuals These sinuses are lined with ciliated mucous membrane which is directly continuous with that of the nasal cavities

The *frontal* sinuses are frequently the seat of suppurative inflammation, which gives rise to pain and tenderness in the supra-orbital region and to a discharge from the corresponding nostril This discharge can be seen coming from beneath the anterior extremity of the middle turbinated bone Owing to the proximity of the opening into the maxillary sinus, pus coming down the hiatus from the frontal sinus may pass into the maxillary sinus, thus simulating disease or producing disease of that cavity too

The *ethmoidal* sinuses or cells, anterior, middle and posterior, three on each side, lie between the sphenoidal sinus posteriorly and the lower extremity of the frontal sinus anteriorly The region of the ethmoidal cells is that from which mucous polyps of the nose take their origin. These polyps are a common accompaniment of suppuration of the accessory nasal cavities Caries affecting the anterior cell of each sinus may extend into the orbit, and the pus may form a fluctuating tumor above the inner canthus of the eye It is to be recalled that a meningocele may be present in this same location

The *sphenoidal* sinuses are the most posterior, lying still farther back than the ethmoidal sinuses They open into the spheno-ethmoidal recess above and posterior to the superior turbinated bone Discharge from them goes into the pharynx and can be seen with the rhinoscopic mirror.

The *maxillary* sinuses lie, one on each side of the nose, beneath the orbit and to the outer side of the nasal fossa The sinus opens into the nose by a slit-like opening into the middle meatus about its center, posterior to the hiatus semilunaris and 1 inch (2.5 cm) above the floor of the nose When the opening is close to the hiatus, liquids may run into it from the hiatus

The inflammatory and infectious diseases of the maxillary sinus originate by extension from either the nose or the teeth The sinus is the seat of tumors, often malignant, and of inflammation, the latter accompanied by an accumulation of mucus or pus The walls of the sinus are thin, so that a tumor, bulging forward, causes a protrusion of the cheek. The tumor presses inward and obstructs the breathing through the side of the nose, or it pushes upward and causes protrusion of the eye by encroaching on the orbit

Perforation. Perforating ulcerations of the bony part of the nasal septum are often due to syphilis, but when the cartilaginous septum only is attacked, the ulceration is probably not due to a specific process. An ulcer of the nasal septum may form and perforation may take place without the patient knowing of its occurrence The symptoms complained of are a sense of dryness, irritation in the nose, the separation of crusts and, occasionally, free epistaxis. When perforation first occurs, there is often a whistling sound caused by the passage of air through the small opening This gives much annoyance to some patients but they can be reassured, since the sound generally ceases when the opening increases to a larger permanent position

Nasal Obstruction. One of the most frequent and most important consequences of nasal disease is obstruction to respiration The harmfulness of mouth breathing entailed in cases of severe disease is definite

Since nasal obstruction is a factor in numerous nasal affections, and since many of its possible consequences are not always recognized, an enumeration of the causes and symptoms is worth while Inactive alae nasi, which permit of diminished ventilation of the nose and arrested development of the nasal passages, lead to deviation of the nasal septum and often to defective development and growth of the upper maxillae with arching of the palate, V-shaped alveolar arch and crowded teeth There is a tendency to frequent and prolonged nasal catarrh and later to hypertrophic rhinitis Postnasal catarrh and increase in adenoid tissue often follow.

Catarrh of the eustachian tubes in either acute or chronic otitis media may develop as a part of the general pathologic processes that follow nasal obstruction

The symptoms of nasal obstruction are difficulty in clearing the nose of mucus, noisy nasal respiration with sniffling, heavy breathing and snoring, loss of nasal resonance, alterations of the voice, anosmia or loss of the sense of smell, and deformity of the thoracic wall Well-developed mouth breathing is associated with a typical facies, dry mouth, spongy gums, imperfect mastication of the food and slowness in eating or necessity of bolting the food

Nerves of the Nose. In addition to the olfactory nerve the nose is supplied by the nasal, infratrochlear, and infra-orbital branches of the fifth nerve, hence the eyes water when the nose is injured In certain cases of neuralgia affecting the ophthalmic division of the fifth nerve, pain is felt along the side of the nose Because the nasal nerve enters the skull from the orbit through the anterior ethmoidal foramen, it may be involved in disease of the ethmoidal sinuses.

Nasal Polyp. Polyps are the commonest tumors of the nose. They are benign tumors which usually do not become malignant, however, they tend to recur after removal

The causes of nasal polyps are unknown These tumors are often associated with hyperplastic rhinitis

Mucous polyps arise from the outer wall and principally from the margin of the middle meatus and the cells of the ethmoidal labyrinth The symptoms of nasal polyp develop slowly and the patient sometimes becomes so gradually accustomed to the condition that the disease is often well marked when the patient is first examined. The symptoms are those of nasal obstruction and its consequences.

Nasopharyngeal Polyp. Nasopharyngeal polyps are usually unilateral and solitary A single polyp in the nasopharynx may have its origin in the antrum and by growth pass into the nose through an accessory ostium maxillare. The symptoms are those caused by one-sided nasal obstruction and catarrh. There is increasing discomfort as the polyp descends into the pharynx

Malignant Tumors. Malignant tumors of the nose are rare. The symptoms of a malignant nasal tumor may commence by the presence of nasal obstruction and discharge, and bleeding spontaneously or on slight manipulation. Spontaneous bleeding occurring in a middle-aged patient arouses suspicion of the presence of malignant disease. The extent to which a malignant tumor has involved the nose or the bones

Inflammation and obstruction may extend to the lacrimal passages, the conjunctival and finally the orbital tissues, producing orbital cellulitis and periostitis. Extension of infections from an accessory sinus may cause a great swelling and ptosis of the eyelids, chronic conjunctivitis, blepharitis, photophobia, dilatation of the pupil and blepharospasm. In such ocular involvements exophthalmos and some impairment of the mobility of the eyes are common. These conditions are serious illnesses and always are accompanied by marked constitutional symptoms, which are manifested by high fever and violent pain in this region.

The aural symptoms arising from a chronic suppuration of the sinuses are tinnitus, vertigo and earache. Noises in the ear as a result of eustachian catarrh may be the first discomfort to attract the patient's attention

Headache, face-ache, hemicrania and neuralgia, though commonly of origins other than the sinuses, often require an exploration of the sinuses Pain in the face arising from sinus disease may present a morning periodicity, increasing for some hours after the patient arises in the morning and often disappearing as the day goes on This periodicity has been explained as the result of accumulation and retention of secretion during the night The secretion then escapes from the cavity during the first hours of physical activity

The diagnosis of chronic sinusitis is made on the basis of the symptoms and of examination for signs of rhinitis, particularly in the region of the ostium of the sinus, together with evidences of discharge in the nose and nasopharynx. The presence of polyps at once points to chronic ethmoiditis In many cases roentgenologic examination will reveal changes in the bone or thickening of the linings of the cavities of the sinuses Roentgenograms of the sinuses often reveal the presence also of hyperplastic thickening of the membranes and of formation of polyps in the sinuses. Finally an exploratory puncture and washing of the sinuses to reveal pus if present may be required for diagnosis.

There are but few physicians left who regard a chronic sinusitis as of much importance as a focus of infection The prognosis is usually for spontaneous recovery or, at least, for temporary alleviation of symptoms

Voice Dynamics and the Ethmosphenoid Epiglottidean Syndrome. The nose and the nasal cavities act as resonating chambers for the voice whereby sounds produced in the larynx are amplified and changed in timbre. A lack of nasal resonance, as observed in nasal obstruction, is termed rhinolalia clausa

The patients complain, usually in the morning, that they are not in good voice. The alteration in voice and the hoarseness clear up during the day. Vocalization and swallowing usually dispose of the effete mass that has accumulated during the night The patient finds it difficult to start phonation, and his throat tires quickly

In some patients the symptoms may be referable to involvement of the muscles of the pharynx and their nerve supply To a singer this may be a devastating malady. Pressure in the laryngeal structure from even a small amount of pus may be sufficient to interfere with the normal emission of the pus by coughing As the disorder advances pus accumulates in large quantities and remains in evidence when the epiglottis is examined

In some patients there may be a partial or total loss of taste or smell, a ticklish and tight feeling about the throat and blocking of the ears, with or without spasmodic cough Less frequently patients hear tingling noises, an echo or a vibration Pus may be found in the nasopharynx, and redness of the tympanic membrane without an impairment of hearing.

Cysts and Benign Tumors of the Sinuses. The maxillary sinuses may contain mucous retention, serous, periodontal or dentigerous cysts. Mucous retention cysts are the common cysts often reported by the roentgenologists. A cyst of the periodontal type arises from the root of a pulpless tooth The bone is eroded from the

Diseases of the Accessory Sinuses. Suppuration may arise primarily from direct infection of an accessory sinus or secondarily from some intranasal disease. Among the acute infectious diseases which give rise to sinusitis are influenza, pneumonia, measles, scarlatina, smallpox, cerebrospinal meningitis, diphtheria, erysipelas and, more rarely, mumps and gonorrhea Coryza and all processes of nasal disease associated with pus formation may induce empyema in the accessory cavities. The anterior group of sinuses is much more frequently affected than are the posterior groups. Of the anterior cells the maxillary sinuses are the ones most often involved, the ethmoidal next, and the frontal sinuses least often

Acute Sinusitis This forms a part of many acute catarrhs which invade the sinuses by direct extension from nasal coryza Acute exacerbations are not uncommon in the course of chronic empyema Bathing in a public swimming pool, particularly if diving is done, may lead to infection of the nose and sinuses Acute sinusitis is generally met with in adult life but is not unknown in childhood.

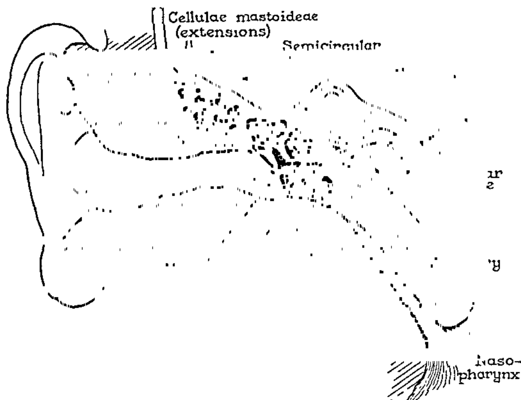
The symptoms of an acute sinusitis frequently form a part of acute nasal coryza. However, if during an acute nasal coryza there occurs pain in the region of a sinus accompanied by tenderness on pressure over the cavity, sinusitis is suspected. Lacrimation, photophobia, edema or a light congestion of the eyelid with proptosis, and deep-seated headache also suggest the implication of a sinus More than one cavity may be affected at the same time The occurrence of a chill or of a rise in temperature would indicate more than a simple catarrh in a patient suffering from acute rhinitis Relief of pain follows a discharge of mucus, which may be bright yellow and blood-stained or mucopurulent, or relief follows a free gush of pus which sometimes is very offensive both to smell and to taste

On examination there is usually evidence of acute rhinitis, or the middle turbinal will be congested, infiltrated and pushed against the septum, and the meatus below it will be clogged with stringy mucus and, later on, with mucopurulent material Transillumination may direct attention to the maxillary sinus, and puffiness of the forehead or fullness or duskiness of the eyelid on one side will point to the frontal or the ethmoidal cavities When the posterior group is affected, the rhinoscopic mirror will show a deeply congested appearance of the pharynx and anterior sphenoidal wall, and mucopus will ultimately be visible above the superior turbinal on the posterior pharyngeal wall Most patients who have acute sinusitis recover spontaneously Complications very rarely result, but sometimes occur during the course of a chronic sinusitis as the result of an acute exacerbation

Chronic Sinusitis Chronic sinusitis in the accessory sinuses is common In many cases roentgenologic examination reveals clouded mucous membrane of the sinuses, but this does not necessarily imply active disease

The maxillary sinuses are those most often affected Patients afflicted with empyema or chronic sinusitis frequently seek relief on account of discharge or of obstruction or of a chronic cold in the head

The symptoms of chronic sinusitis may be grouped as (1) nasal symptoms, (2) nasopharyngeal symptoms, (3) ocular symptoms, (4) aural symptoms and (5) headaches



The nasal symptoms are nasal obstruction and nasal discharges The obstruction may be unilateral or bilateral. It is usually more marked in the morning hours than at other periods and is more intense with the increase of nasal inflammation The discharges may flow posteriorly and the obstruction may be slight and the secretion scant in amount so that the patient for years has swallowed it unconsciously Disorders of the senses of smell and taste are often indicative of the disease There may be parosmia or anosmia, or there may be kakosmia. The presence of kakosmia is suggestive of sinus suppuration. The patient is seldom aware of the odor.

The symptoms in the nasopharynx and the larynx are those of a postnasal irritation or low-grade inflammation.

and frostbite is therefore common. Injuries and wounds of the cartilage occur readily and are slow to heal.

Discoloration. A livid or *bluish* tint of the external ear is usually indicative of general cyanosis A frostbitten ear is at first white, but when it becomes thawed the skin is cyanotic. A *blue-black* discoloration of the cartilages of the ear occurs in ochronosis (usually with alkaptonuria). A swollen, discolored pinna may be due to *injury* or *hematoma.*

Angioma, or enlargement of the blood vessels, not infrequently affects the external ear and not only may disfigure but also may show a tendency to extension to the scalp, face and neck In some instances these angiomas are jet black and fissured, and contain hair

Fig 4-3 The ear

The External Meatus. The external auditory meatus extends from the concha to the drum head (Fig 4-3) In order to look into the ear and see the membrane, it is necessary to straighten the canal by pulling the auricle outward, upward and backward The general direction of the canal in the adult person is from without, downward, inward and slightly forward In a child upward traction is not so necessary as in the adult In childhood the length of the canal is approximately the same as in adult life, but the bony part is still in a cartilaginous condition.

The external opening of the meatus is oval, but farther in, the canal is more nearly circular In examining the meatus, the otoscopic attachment of an ophthalmoscope or a speculum and head mirror are used.

Below and in front of the ear is the temporomaxillary joint, and just posterior is the glenoid lobe of the parotid gland. When the gland is inflamed and swollen, it presses on the cartilaginous canal and produces pain; and in case of suppuration,

tooth to the sinus by means of granulation tissue formation. Dentigerous cysts are of congenital origin and are mentioned in association with tumors of dental origin

These cysts do not produce symptoms unless they have attained space-occupying proportions sufficient to give pressure symptoms The symptoms consist of pain. There may be swelling of the cheek and bulging of the lateral part of the adjacent nasal cavity Diagnosis is established by roentgenographic examinations and needle puncture Small cysts require no treatment.

Papillomas, adenomas, lipomas, hemangiomas, osteomas, chondromas, gliomas and mixed tumors occur mainly in the frontal and ethmoidal sinuses. These tumors usually do not give symptoms until they have occupied all the available space in the sinus. After this they produce symptoms from pressure and by eroding adjacent bone and interfering with the function of other organs, such as causing a unilateral exophthalmos by extending into the orbit

Malignant Tumors of the Sinuses. Malignant tumors which affect either the paranasal sinuses or the nasal cavities as a rule arise in the sinuses. These tumors, consisting equally of carcinomas and sarcomas, arise most frequently in the maxillary sinuses. However, they do arise in the ethmoidal and the frontal sinuses

When the tumor extends from the sinus, it erodes bone There is pain, and often there are severe epistaxis and nasal obstruction A purulent bloody nasal discharge is common. Malignant tumors in the antrum cause pain in the teeth and cheeks, sensory disturbances of the skin, and swelling of the cheek. There is often bulging into the nose and hard palate, or unilateral exophthalmos The lymph nodes on the ipsilateral side are enlarged, and metastasis ensues to distant regions.

The diagnosis is made on the basis of roentgenographic studies which reveal a mass or defect in the bones of the affected sinus Biopsy of tissue from the sinus or from the nose is conclusive

Malignant Tumors of the Nasopharynx. Malignant tumors of the nasopharynx are usually highly anaplastic carcinomas, usually designated by such terms as lympho-epithelioma or transitional-cell carcinoma They metastasize early, and it is usually the metastatic lesions that first attract attention—swelling in the neck, or pain or deafness in one ear Headache, sore throat, epistaxis and nasal obstruction are frequent complaints Cranial nerves may become involved, with resultant diplopia or optic atrophy Signs due to involvement of the fifth, seventh and other cranial nerves are occasionally demonstrable The local lesion in nasopharyngeal lympho-epithelioma may escape detection by expert otolaryngologists for as long as 6 months after the tumor has been histologically identified in a metastatic cervical node

THE EAR

The external ear (auricle, pinna) is composed mainly of a cartilaginous framework covered with thin skin The lobe, which is the lower part of the ear, is composed of dense connective tissue containing fat The large concavity leading into the meatus is the concha

The external auditory meatus, the tympanum and the eustachian tube are formed from the first branchial cleft in the fetus A failure of any portion of the cleft to close normally may leave small sinuses or depressions in the neighborhood of the ear and these may persist after birth as congenital fistulas More severe deformities may result from cleft abnormalities resulting in absences of parts or all of the ear

Ears that are unusually prominent, long or misplaced, with absence of helix, anthelix or lobule, are marks of imperfect physical development. These abnormalities do not necessarily carry stigmas of degeneration An unusual protrusion of large auricles from the sides of the head is the commonest of all ear deformities.

The loss of the auricle does not cause much, if any, decrease in sound perception. The subcutaneous tissue of the ear is well supplied with blood Owing to the absence of fat, the exposed condition of the blood vessels renders the ear sensitive to cold,

Neuralgia, or recurring pain in one ear similar to the episodes of pain from tic douloureux, is experienced. Arthritis of the temporomaxillary articulation is accompanied by earache. Angina pectoris and, if in the right ear, aneurysm of the innominate artery, may give earache. Affections of the tongue may be accompanied by otalgia. Herpes zoster oticus may be preceded or followed by severe pain in the ear.

Discharges From the Ear. A fracture of the base of the skull may cause an aural hemorrhage, followed by the escape of *clear cerebrospinal fluid.*

Rupture of the tympanic membrane, either as a result of injury or consequent on otitis media, may be responsible for a discharge of *blood.*

A flow of *pus,* otorrhea, may be either acute or chronic and while it may be due to a polyp or abscess of the external meatus, it is, in the majority of cases, an evidence of otitis media with or without complication.

Diseases of the Membrana Tympani. Reflected light from a head mirror or an otoscope directed through the meatus by a speculum reveals the membrana tympani Extending downward from its center is a small cone of light Any depression or bulging of the membrane will cause this cone of light to be altered in its position or not be present at all. From the center of the membrane upward extends a line which indicates the point of attachment of the long handle of the malleus Stretching across the upper portion is the membrana flaccida.

During the course of acute rhinitis, pharyngitis or influenza, blebs or bullae filled with blood serum or blood may develop in the skin of the deep portion of the external canal and on the drum. These may be present before there are symptoms of otitis media. The blebs appear as purple blisters which break at touch and yield bloody serum, leaving the skin or the drum wet and red Soon the blebs break and cause a thin bloody discharge. Often synchronously with the sanguineous discharge from the ear there is relief of the pain

Rupture. The ear drum may be ruptured by the introduction into the canal of pins or sticks for scratching or removal of wax, flat-handed slaps or boxes on the ear; the compression of explosion, as by artillery fire, too rapid decompression, as occurs in divers and in occupants of aircraft after rapid descent from high altitudes

The symptoms of ruptured drum are sudden and intense pain in the ear followed by deafness, loud tinnitus and perhaps vertigo, nausea and vomiting If infection follows and acute otitis develops, otoscopic examination reveals fresh or dry blood in the canal and on the drum The perforation may be visible Bloody crusts in and about the ruptured membrane will be present for several days. Increasing pain, fever and a seropurulent discharge denote the presence of otitis media

Diseases of the Middle Ear. Otitis Media *(Infections of the Middle Ear).* Infections of the middle ear pass up the eustachian tube from the pharynx and the nasal cavities. The infection may pass thence to the mastoid antrum and mastoid cells On pus formation and suppuration of the middle ear the pus usually obtains an exit by perforating the tympanic membrane and discharging through the external auditory meatus

In instances of retropharyngeal abscess or suppuration of the middle ear pus may pass down the eustachian tube and escape through the nose

In a retropharyngeal abscess originating in a vertebra the pus may pass through the fascia or behind it, extend laterally and appear under the sternocleidomastoid muscle While behind the fascia, the pus may be in contact with the base of the skull, and if so the infection may pass through the porous bone and involve the meninges and the brain In rare instances the pus may perforate the bone below and anteriorly and involve the jugular vein and the internal carotid artery.

In suppurations of the middle ear, if the posterior bony wall of the auricular canal is perforated, the infection may involve the facial nerve with facial paralysis ensuing The brain also may be reached by the infection extending through the internal ear through the fenestra ovalis and rotunda, and the internal meatus, and

pus may discharge through the external meatus, gaining access to the canal through fissures in the cartilage. The cartilaginous portion of the meatus contains sweat glands, sebaceous glands and hair follicles. There are only a few glands in the upper posterior portion of the bony meatus.

Impaction of Cerumen. Cerumen is the normal secretion of special ceruminous glands in the cartilaginous portion of the external auditory canal. Excessive accumulations of cerumen may give symptoms When symptoms are present, the mass has formed, and it may then move with motion of the head or may swell on the entrance of sweat or water and produce complete obstruction A complete obstruction causes deafness, tinnitus and a full, stopped-up feeling in the ear. At times there is a cough from a vagus nerve stimulation There may be pain or vertigo if the mass presses against the drum If the auditory canal has been filled with the wax, there may be dilatation of the canal, or erosion of the skin and granulation tissue may result. Bleeding ensues on removal of the wax, healing follows readily.

Furuncle. A furuncle of the external auditory canal is due either to the entrance of pyogenic organisms into the subcutaneous tissue by way of hair roots or follicles or to an infection of sweat glands

The commonest predisposing cause of furuncle of the auditory canal is an acute or a chronic dermatitis of the canal The process begins with pain of increasing intensity in the ear with throbbing, there is pain on movement of the lower jaw, and wide opening of the mouth may be impossible because of the pain Local pressure on the pinna, or auricle, or motion of this part is painful There may be a general aching and at times a fever

The diagnosis of furuncle of the auditory canal is made easily on inspection of the canal, especially if the ear drum is not congested or is not perforated. A roentgenologic examination should be made if there is doubt about involvement of the mastoid cells

External Otitis. Some forms of external otitis may be due to otomycosis An otomycosis is usually an accompaniment of a mycotic infection of the skin. The ear feels sore and tender, chewing may be painful The auditory canal often contains soft semifluid wax and debris of flecks of a white foamy substance. As the disease progresses, the ear is tender, and chewing is painful. The canal is sometimes completely filled with soft, moist, sebaceous-like detritus, which often has a greenish color due to a secondary infection After the ear has been cleansed, the canal wall is found to be red, with excoriation of the epithelial lining The drum is not affected In the severely affected ear the canal is swollen, often obliterated and very painful. The pain is worse at night than by day and there may be fever An otomycosis is diagnosed by identifying the fungus in the discharges from the affected ears.

The external auditory canal is affected in many forms of dermatosis

Pain in the Ear. Earache. USUAL CAUSES. The most frequent cause of severe pain in the ear (earache) is otitis media secondary to many illnesses such as scarlet fever, epidemic influenza, acute simple rhinopharyngitis or tonsillitis, measles or diphtheria. It is commonest in children and may explain an obscure infantile illness with fever

OTHER CAUSES. Pain referred to the ear or about the mastoid process when there is no local cause for such symptoms is a reflex or referred otalgia Common causes of these secondary otalgias are exposed dentine and inflamed pulp or dying nerves of the teeth on the same side, particularly in the mandibula; unerupted, impacted or infected molar and wisdom teeth which may cause severe, deep, boring earache of long duration. Acute inflammation or ulcerative processes exposing nerve ends in the nasopharynx, pharynx, laryngopharynx and larynx may give rise to otalgia Malignant growths, even small ones, of the nasopharynx are prone to cause this symptom. A sphenopalatine ganglion neuralgia often causes pain in the ear or in the region of the emissary vein on the posterior surface of the mastoid process.

persistent mucopurulent discharge constantly or intermittently. In such a condition healing may eventually take place but there is permanent impairment of hearing Owing to impairment of function of an injured labyrinth, an impairment of hearing may become manifest after all signs of infection have ceased

The serious complications of acute otitis media are suppurative mastoiditis, serous or purulent labyrinthitis, meningitis, extradural brain abscess and lateral sinus thrombosis.

Suppurative Mastoiditis. Suppurative mastoiditis is a complication of otitis media or it occasionally occurs after fractures of the skull. Once the infection is established in the mastoid cells, it tends to persist and to suppurate

The common etiologic agent is the hemolytic streptococcus However, any one of the pyogenic organisms may be present such as the staphylococcus or the pneumococcus.

There is a rapid vascular engorgement with edema and infiltration and the production of a mucopurulent exudate The mucosal cells degenerate, so that the bone is deprived of blood supply, and the cell walls disintegrate. Large cavities are present in the well-pneumatized mastoid form and if the cortex is thin or thinned, perforation ensues If the aditus and antrum are large enough to furnish adequate drainage into the middle ear, resolution can take place.

The symptoms depend on the severity of the suppurative process Pain is present in the ear and over the mastoid area. Fever (temperature up to 103 F or more) which is present for several days may then subside except for afternoon rises The recurrence and the continuation of the fever indicate a more severe process. There are nausea, vomiting, anorexia, constipation and increasing weakness.

Tenderness, which may be widespread, is present over the mastoid antrum There is often edema of the skin and soft parts, and swelling of the posterosuperior wall of the external auditory canal. The tympanic membrane is bulging and perforated. There is often deafness of the conduction type without tinnitus.

A polymorphonuclear leukocytosis is the rule. The urine may contain albumin, depending on the amount of fever The roentgenogram reveals the degree of bone changes as well as the degree of pneumatization of the cells. The latter is helpful in determining prognosis, for the highly pneumatized cells are more easily and widely destroyed.

Labyrinthitis. The labyrinth is often affected from the toxic agents of infections without the entrance of bacteria. Bacteria may enter the labyrinth as the result of trauma, surgical or otherwise, or from middle ear disease In widespread labyrinthitis there may be destruction of essential structures and loss of function

The invasion of the cochlear portion of the labyrinth causes tinnitus and deafness Invasion of the vestibular apparatus produces varying degrees of vertigo, nystagmus, temporal or retro-ocular headache, vomiting and mild weakness of the facial muscles In diffuse involvement of the labyrinth the patient becomes very ill with severe vertigo which makes it impossible to stand alone. The patient lies absolutely still The room seems to turn toward the diseased ear. The slightest movement brings on violent vomiting

The diagnosis of labyrinthitis depends on the accurate testing and evaluation of the turning, caloric and fistula tests by one trained in employing these tests and interpreting the findings Acutely ill patients are not subjected to these tests

Tuberculosis. Tuberculosis of the middle ear is rare except in young adults during the advanced stages of pulmonary tuberculosis. The infection seems to be brought to the ear as a blood-borne infection or when there are serious deep lesions of the pharynx or nasopharynx In the latter instances the infection reaches the ear through the eustachian tube.

Once in the ear, a tuberculous infection causes widespread destruction of the tympanic membrane, auditory tube, mastoid cells, and bone of the labyrinth. In-

then to the brain. The infection may extend to the attic and the antrum and perforate the roof of these structures and form a subdural abscess in the middle cerebral fossa. Extension of an inflammation from the antrum and mastoid cells may enter the posterior cerebral fossa to involve the lateral sinus, causing a lateral sinus thrombosis, or produce a cerebellar abscess

ACUTE OTITIS MEDIA. In an acute otitis media the fluid content of the middle ear is either serous or purulent Mild infections of the middle ear occur which do not perforate the tympanic membrane. When the fluid of the middle ear is serous, the otitis may be of allergic origin. However, all forms of otitis media are to be considered infectious in origin until proved different. The bacteria most commonly involved are the hemolytic streptococci, the *Hemophilus influenzae* and all forms of pneumococci, staphylococci, and, in rare instances, such organisms as the *Klebsiella pneumoniae*. In most cases these organisms enter the auditory canal through ethmoid cells or through the eustachian tube by continuity of tissue, aided by such mechanical devices as blowing of the nose, sneezing and coughing In instances in which the drum has been perforated previously, the organisms may enter from the external auditory canal. *However, in most instances of acute inflammations of the middle* ear the organisms enter from the nasal cavities, the paranasal sinuses, the nasopharynx and the pharynx

In the beginning of otitis media the pain may be mild, but as the inflammatory process spreads, the pain becomes more severe The pain is often the boring, lancinating type that spreads into the occiput, temples and teeth and is made worse by *coughing, sneezing or swallowing Except in very mild infections there is fever.* The height of the fever indicates to some extent the severity of the infection· In mild cases the temperature will reach 101 or 102 F (38 3 or 38.9 C); in severe infection it may be as high as 104 F (40 C) The fever usually continues 4 or 5 days with morning remissions and ceases by lysis Synchronous with the onset of the fever there are malaise, anorexia, vomiting, pain in the back and limbs and constipation The *pain, and often the fever, disappears on perforation of the drum*

The drum is usually retracted It may appear injected or may have a grayish color or a yellow cast and often is shiny. At times bubbles of fluid or a fluid meniscus may be visible through the tympanic membrane.

CHRONIC SUPPURATIVE OTITIS MEDIA Chronic suppurative otitis media is manifested by an intermittent, purulent discharge from the ear, which accompanies respiratory infections During acute exacerbations the discharge from the ear increases During an exacerbation, if the discharge stops, often there are pain and fever.

The diagnosis is established by otoscopic examination. The perforation of the drum is identified A central perforation without involvement of the annulus tympanicus differentiates this form of otitis media from the more severe forms

The perforation of the tympanic membrane in the severe necrotic types of otitis involves the peripheral parts of the drum. The opening is irregular in shape and may represent destruction of from one half to two thirds of the drum There may be granulation tissue or a polyp inside the perforation

Masses of debris appearing on the attic and the tympanic atrium which arise from squamous epithelium growing through the perforation in the drum are known as *cholesteatoma*. The term is derived from the content of fat and cholesterol of the masses of debris.

The perforation may be a large defect in the tympanic membrane through which the promontory of the ossicles may be visible. Deafness of the conduction type is variable in its severity Roentgenologic examination may reveal a nonpneumatized type of mastoid process.

COMPLICATIONS OF OTITIS MEDIA The complications of otitis media depend on the severity of the disease. The *infectious* process may become subacute with a

vertigo of central nervous system origin develops slowly over a long period. There may be associated nystagmus and falling. The diagnosis of these lesions, however, lies within the field of neurology and neurotology.

Types of Dizziness and Vertigo. DeWeese emphasized that it is not wise to focus all of the attention on hearing and labyrinthine function, for in the great majority of patients complaining of dizziness the results of functional examination of the ear will be normal.

Cerebral anoxemia may produce dizziness. Arteriosclerosis and hypertensive cardiovascular disease often produce a constant feeling of uncertainty or intermittent mild attacks of dizziness. In postural hypotension dizziness occurs when the patient rises suddenly from a recumbent or sitting position to the standing position. Pernicious anemia or any severe anemia may produce transient or recurrent dizziness as a result of cerebral anoxemia

Sudden and more prolonged cerebral anoxemias are produced by paroxysmal auricular fibrillation; aortic stenosis with insufficiency, arteriosclerotic heart disease (Adams-Stokes disease), and carotid sinus hypersensitivity. In some cases of dizziness from these causes it may be necessary to withhold a final opinion until the patient can be observed during an attack.

Dizziness is not a feature of brain tumor or other destructive disease inside the calvarium unless there is depression of function of the inner ear on one or both sides. Dizziness is a feature of lesions of the cerebellopontine angle and of the brain stem In cerebellopontine angle lesions there is loss of hearing, tinnitus, corneal anesthesia, fifth and seventh cranial nerve involvement, ataxia, and intracranial hypertension.

Chronic and recurring dizziness cannot be attributed to head injuries unless there is a persistent loss of hearing in a patient who had normal hearing prior to the accident. However, concussion can give rise to dizziness, tinnitus, headache and other symptoms without any positive physical findings perhaps as the result of multiple small hemorrhages. Compensation neurosis and outright malingering are common and may cause diagnostic difficulties in those who have had head injuries.

In labyrinthine hydrops there are paroxysmal attacks of whirling vertigo, usually with abrupt onset, almost always accompanied with nausea and vomiting These attacks last an hour or two and subside There is complete freedom from vertigo between attacks There is an accompanying perceptive hearing loss, frequently fluctuating, almost always progressive and usually more severe in one ear than in the other. Tinnitus, most commonly persistent between attacks and frequently fluctuating, is present The associated hearing loss is often a flat, low-tone perceptive loss, and the caloric reaction is hypoactive

Acute toxic labyrinthitis often follows an acute febrile disease, indiscretion in consumption of food or alcohol, or the use of any type of drug. In this syndrome there is a gradually increasing whirling vertigo lasting 1 to 3 days, followed by a slow subsidence of symptoms within a period of a week. There is no associated hearing loss or tinnitus

When the end-organ is suddenly and completely destroyed, either by injury or by hemorrhage, there are a sudden, overwhelming vertigo, nausea, vomiting, loud tinnitus and complete loss of hearing A slow compensation takes place over a period of 10 to 20 days, and gradually the opposite labyrinth controls reasonably well the function previously presided over by both labyrinths.

The commonest cause of dizziness is a functional disorder. The diagnosis should be made on the basis of positive evidences of the existing neurosis This is one of the most important diagnoses to be made, lest there be created an iatrogenic disorder.

Ménière's Disease. Ménière's disease is characterized by sudden attacks of vertigo, with tinnitus or incomplete deafness in one or both ears.

Ménière's disease may be attributable to disease of the labyrinth either hemor-

vasion of the facial canal and paralysis of the facial nerve ensue. A destructive form of labyrinthitis with deafness may occur. These widespread destructions may take place with a minimum of symptoms.

Examination discloses that the drum is perforated and discharges a foul purulent material. There is a perception type of deafness. The diagnosis is established by the demonstration of tubercle bacilli on culture and by guinea pig inoculation of the suspected material

Syphilis. Congenital syphilis frequently engenders deafness by destruction of the cochlea and semicircular canal apparatus Infants thus affected are born with total deafness. In some instances of congenital syphilis, osteomyelitis of the labyrinth or syphilitic neuritis of the cochlear nerve does not occur until between the fifth and fifteenth years of life.

The diagnosis is based on the history and the presence of Hutchinson's triad: (1) interstitial keratitis, (2) Hutchinson's teeth and (3) deafness Often perforation of the bony part of the nasal septum is present.

In acute acquired tertiary syphilis which is present in the nasopharynx the process will extend to the membrana tympani Generally such an extension is made by pyogenic organisms rather than by the *Treponema pallidum*. Once in the ear, the syphilitic process is very destructive The labyrinth is destroyed and sequestra are formed There is a profuse purulent discharge from the middle ear There are severe labyrinthine symptoms which soon subside as total deafness ensues. The diagnosis is established from the history, the examination, and the strongly positive serologic reactions

Tinnitus. Subjective sounds heard in the ear are tinnitus aurium Sounds which are vaguely situated in the head are tinnitus cerebri. Sounds of either type are usually heard on one side only and are described variously by the patient.

Tinnitus is a common symptom and may be due to so many conditions that in a given case it is often impossible to determine its cause. Tinnitus is a response of the auditory part of the eighth cranial nerve to abnormal stimuli

It is helpful to bear in mind that the most frequent causes of tinnitus, usually ringing in the ear, as described by the patient, are psychoneurosis with anxiety and consequent vasomotor irregularity, diseases of the ear such as impacted cerumen, otitis with fluid in the middle ear, and obstruction of the eustachian tube; blood diseases, as in anemias and senescence An attack of migraine is frequently preceded by or accompanied with sudden loud noises

Tinnitus with deafness may be due to the administration of quinine, as well as salicylic acid and its compounds Ergot in considerable doses may give rise to ringing in the ears because of its probable action in producing cerebral anemia. Various subjective sounds, due to toxemia, circulatory disturbances or aural disease, may be present in some of the *infections*, particularly cholera, malaria and rickettsial fevers

Tinnitus or ringing in the ear is a symptom of ear disease in 8 out of 10 patients affected with otologic disorder. When tinnitus is associated with an otologic disease, there is always an accompanying deafness, which may be slight, low-pitched, roaring or rumbling, constant or throbbing, or high-pitched, whistling or ringing

Unilateral tinnitus and very severe or total deafness of the perception and nerve type, with or without vomiting and vertigo, followed by numbness in the face, diplopia, occipital-frontal pain, stiffness of the posterior neck muscles, unsteady gait and ataxia, choked optic nerve head, loss of corneal reflex, weakness of the lower part of the face of the same side, with a dead labyrinth on a caloric test and Kernig's sign, are highly suggestive of an expanding intracranial tumor or, if there is fever, a brain abscess.

Vertigo. True vertigo may be caused by labyrinthine disease, lesions of the central nervous system such as acoustic tumor and cerebellar disease. Often the

ing which follows inflammation of the middle ear resulting from simple or specific infectious rhinopharyngitis, postnasal adenoids, enlarged faucial tonsils, nasal polyps, and nasal stenosis from any cause. Wax in the meatus, aural polyps, parotitis or other inflammations and growths may produce deafness by closing the external meatus. A unilateral deafness of sudden onset is often of central origin. During the course of meningococcic meningitis or meningoencephalitis, typhoid fever, influenza, scarlet fever or measles, deafness may occur which follows the destruction of the nerves, the nerve ganglia or the structures of the labyrinth by the meningeal inflammation

With advancing age there is a loss of hearing for high-pitched tones, deafness of the nerve type with tinnitus in one or both ears.

Overuse or hypersensitiveness to quinine and salicylates may cause a degeneration of the nerve cells. The use of these drugs during pregnancy may affect the unborn child through the placental circulation. In lead poisoning the lead may act on the vessels of the cochlea and on the brain Phosphorus, carbon monoxide, chenopodium, arsenic, mercury, morphine and aniline dyes have produced nerve deafness. Streptomycin at times seems to have a specific transitory toxic effect on the cochlea and vestibular branches of the auditory nerve. The deafness and tinnitus caused by streptomycin usually disappear after its discontinuance However, the vestibular effects of the drug often are permanent

Permanent deafness may begin abruptly on the fourth and fifth days of epidemic parotitis (mumps).

Hemorrhage into the labyrinth, if both divisions of the eighth nerve are involved, may produce sudden but permanent deafness and loss of function of the semicircular canal apparatus, since it destroys the essential end-organs.

Traumatic and *occupational deafness* may occur as a result of different forms of acoustic trauma; as a blast injury or prolonged exposure to loud noises. In hysteria and malingering mere pretense of deafness is common.

The distinction between ordinary middle-ear deafness and nerve deafness is made by testing with a watch or a vibrating tuning fork. If the deafness is due to *aural disease*, the ticking of a watch or the vibrations of the tuning fork are heard faintly or not at all when the instrument is held at varying distances from the ear, these noises become distinctly audible when the watch or the handle of the tuning fork is placed in contact with the skull or the mastoid process (bone conduction). The sound is heard best by the nonaffected ear if deafness is due to disease of the auditory passages, by the affected ear if deafness is due to obstruction of the air passages. In *nerve deafness* the watch and the fork are heard indistinctly or not at all, either in contact or at a distance In ordinary deafness the nerve is normal and can appreciate vibrations brought by the bone, but through some fault in the mechanism aerial vibrations are not transmitted to the nerve endings In nerve deafness the nerve is at fault and cannot appreciate vibrations, no matter how well they may be conducted.

The *Weber test* determines whether nonaural impairment is of obstructive or nervous origin by comparing the bone conduction of the two ears by means of a tuning fork.

The *Rinne test* is used to compare the duration of bone conduction with that of air conduction for the ear being tested The patient is Rinne positive when air conduction is greater than bone conduction The patient is Rinne negative when bone conduction is greater than air conduction

Otosclerosis. In otosclerosis there is the formation of new soft bone in the capsule of the labyrinth which replaces the normal bone, with ensuing progressive deafness due to fixation of the footplate of the stapes.

Otosclerosis is a distinct nosologic entity due to a genetic mutation with dominant characters. In the heterozygous state otosclerosis rarely becomes manifest; if it does, it is less severe than in the homozygous state and appears only at advanced age This genetic factor may not be manifest for several generations, but despite this, histologic examination of the organ of hearing reveals the existence of otosclerotic foci.

The clinical manifestations of heterozygous otosclerosis can be influenced by

rhagic or degenerative; to hydrops of the labyrinth; to suppurative or other disease of the middle ear; to a vasomotor disturbance of the vessels of the semicircular canals which may accompany a neurosis, and to disease of the centers of hearing and equilibration.

The vertigo of Ménière's disease is sudden in its onset, and the patient may fall before there is time to prevent it. There may be a transitory loss of consciousness. The face is pale and covered with perspiration Nausea and vomiting ensue. There is present a tinnitus which may consist of hissing, buzzing, roaring or throbbing noises The attacks tend to recur several times in a day, or may be months apart Rare symptoms during the attack are diplopia and nystagmus, double vision, or oscillatory movements of the eyeballs The deafness usually is progressive but incomplete, affecting one or both ears In intervals between the attacks there may be few symptoms, but a continuous giddiness is a common complaint

In those who have symptoms of Ménière's disease a test of the reaction of the vestibular function and the testing of hearing are necessary. The determination of the function of the vestibular portion of the end-organ as it functions through the semicircular canals is obtained through the Bárány test (caloric test)

The value of the caloric test (Bárány's symptom) depends on stimulating the endolymph in the semicircular canals to move. On sudden movement of the endolymph in a normal individual, nystagmus and vertigo ensue The stimulus is effected by turning the subject, or by instilling hot or cold water into the external auditory canal in order to change the temperature of the endolymph

In carrying out the turning test, the subject is turned in a special chair, with head in proper position, at a certain rate of speed and for a definite number of times The caloric test is conducted by instilling cold water (68 F, 20 C) or hot water (112 F, 44.4 C) into the external auditory canal By either the turning or the caloric procedure nystagmus and vertigo of definite types and duration will be produced in normal persons Absence of reactions or change in character of reactions has pathologic significance. Interpretations of the abnormal reactions must be made by those experienced in conducting the test. This test should not be used when the ear drum is perforated

Diagnosis depends on the history and the positive findings as recorded and interpreted

Motion Sickness. The essential cause of motion sickness, for example seasickness, train sickness or air sickness, is the abnormal stimulation of the vestibular apparatus by the unusual motion to which the patient is subjected. Psychic influe[illegible] part in the production of motion sickness. Stimulation of the semi[illegible] symptoms, this occurs, for example, dur[illegible] drops in a down draft The symptoms are [illegible] sometimes diarrhea, with intense headache and mental depre[illegible] the vomiting and diarrhea may produce profound dehydration, and the lack of food intake may cause *acidosis, so that shock ensues.*

Deafness. The hearing mechanism consists of two portions, the conductor and the receptor. The external ear and the middle ear represent the conductor; the internal ear represents the receptor

More instances of deafness result from advancing years than from disease of the tympanic membrane, the middle ear or the eustachian tube. Disease of the auditory nerve, its nucleus, or its cortical center gives origin to nerve deafness Often no cause at all can be found to account for deafness Deafness may be congenital or acquired.

Congenital deafness may result from defects in development of the hearing apparatus as the result of intra-uterine syphilis or German measles or from the administration of quinine to the mother prior to the birth of the child. Congenital deafness often coexists with deaf-mutism

Acquired deafness usually results from loss or impairment of the power of hear-

The color of the eye is not a simple hereditary component. For instance, of blue eyes alone there are 9 shades or classes, which are transmitted in heredity in no less than 45 possible combinations.

The Palpebral Fissure; the Eyelashes and Eyebrows. The breadth or the transverse diameter between the openings of the eyelids is the palpebral fissure. The palpebral fissure varies racially as follows: narrowest in the Mongolian peoples, widest in the whites, and intermediate in the Negroes. The height of the upper lid is classed as low, mid and high. This measurement decreases with age, owing to growth of the facial skeleton and development of the supra-orbital complex.

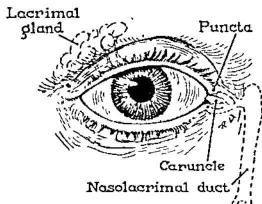

Fig 4-4 Region of the eye

The eyelashes and the eyebrows vary greatly among individuals in appearance and color. They are not always the same color as the hair. In men the color of the beard corresponds with the color of the hair, except that red beards may occur when the hair is dark. Eyelashes and particularly eyebrows add much to the physiognomic effect of the face. In women the eyelashes and eyebrows are so altered cosmetically that descriptions of their natural appearance are nullified Women tweezer off or paint on eyebrows to suit their particular type of beauty. They may glue on false eyelashes

With the advent of middle age a man may be made aware of his years by the barber saying, "Shall I trim the eyebrows, sir?" In other words, a brief description of beginning old age in men is, the time when hair begins to grow where it should not be, and ceases to grow where it should be

Headache of Ocular Origin. Unilateral head pain of ocular origin is common Pain radiating through one eye may be due to a ciliary spasm, localized neuralgia or the spasm of a single ocular muscle A shooting, knifelike, intermittent, stabbing pain, when due to ciliary spasm or a spasm of a single muscle, is associated with the use of the eyes Localized viral disease along nerve trunks may cause prolonged local pain Postneuritic pain may be severe Inflammation of the gasserian ganglion and irritation of the internal carotid artery from aneurysm are uncommon causes of eye pain Glaucoma is often the source of unilateral or bilateral eye pain.

Nearsighted persons do not have headache or head pain unless the nearsightedness is unequal or severe or unless they are abusing their eyes. Abuse in the use of nearsighted eyes may produce severe headache, nausea, and vomiting

Farsighted persons are likely to have frontal headaches which are moderate to severe and are present almost daily in the afternoon or evening. Farsightedness sometimes is definitely associated with certain types of work

If there is an inequality in the amount of error in the two eyes, the pain may be severer over one eye and commoner as a cause of headache.

Errors in refraction usually produce frontal, vertical or bitemporal pain, which may be associated with slight dizziness Nausea is usually relieved by going to bed or resting or taking a single tablet of acetylsalicylic acid. It is made worse by sewing, playing cards and other close application. An error of refraction associated with a muscle error is almost certain to produce symptoms of headache, such as pain or nervousness, irritability, exhaustion, nausea and loss of weight The ophthalmologist is uncertain about a patient's muscle balance if the patient has some constitutional

exogenous factors and also by endogenous milieu. These factors, especially the endogenous milieu, will precipitate the manifestations at an earlier age even in those who have been conditioned for this sort of deafness.

The manifestations consist of a progressive loss of hearing for low tones by air conduction with or without tinnitus There is an apparent improvement of the hearing when exposed to noise (paracusis willisiana). However, the loss of hearing does not vary from day to day except for its progression toward deafness. Eventually there is deafness of a mixed form

The findings on examination depend on the progress of the disease There is present conduction deafness in both ears without a previous history or findings suggestive of otitic suppuration in a patient of less than 30 years of age. The genealogic history reveals that a similar form of deafness may have been present in previous generations. In all, the deafness has progressed more rapidly during gestation or serious illnesses than at other periods. Owing to nerve degeneration there is finally an impairment of hearing of the mixed form

Interpretation of Hearing Tests. Guild has expressed the opinion that nothing is gained clinically by making hearing tests which cannot be interpreted with reasonable certainty in terms of causative lesions In other words, if there be no histologic evidence to support or to refute the diagnostic interpretations customarily made of the data obtained by most of the elaborate, time-consuming technics, in the interpretation of these technics only a description of the kinds of hearing defects found by the tests made and not a diagnosis is given Guild has expressed an opinion that for most patients a few simple tests of hearing afford all the information the clinical otologist needs to supplement or to confirm the impressions gained from the history and the physical examination, and has reached the conclusion that a clear distinction should be made between tests for research purposes and tests for clinical purposes.

The histologic findings in instances of conduction deafness of similar degree as given by Guild lend emphasis to the statements that the practical conclusion is that despite any advances in methods of testing hearing, reliance on the clinical history and the physical examination must continue in order to determine why a patient is hard of hearing and what can or should be done about it

THE EYE

The signs and symptoms referable to the eye are of importance not only from the standpoint of disability from eye disease but also with reference to disorders of the nervous system and in connection with diseases of other organs

The Color of the Eye. The pigment of the eye is contained in the conjunctiva, the sclera, the iris, the choroid, the ciliary processes and the retina The color of the eye ranges from brown through gray and green to blue The lack of pigmentation of the eye in albinism is abnormal but not pathologic The impairment of vision produced by albinism is mainly due to photophobia and nystagmus

There are three major types of distribution of the pigment of the eye the mixed, the rayed and the zoned In the eye of *mixed* colors the periphery of the iris is of some light clear shade, specks or dots or perhaps strands of different color, sometimes variations of the color of the iris, but commonly brown, yellow or orange, encircle the pupil *In the rayed* eye the pigmentation varies in intensity and radiates from the pupil somewhat in the manner of spokes from the hub of a wheel In the *zoned* eye the pigmented part of the iris is a well-defined band around the pupil, the periphery is gray, green, blue or yellowish

In the newborn the eyes are blue or violet As a child grows, the area around the pupil becomes pigmented so that a brown areola and a light background are characteristic. Among European peoples the color of the eyes darkens during adolescence. In general, the coloring of the eyes tends to keep pace with darkening of the hair. In the aged the coloring of the eyes decreases and the eyes appear faded.

Ectropion. Ectropion is an eversion of the eyelid with exposure of the conjunctival surface of the lids; it may affect both lids. The condition is secondary to scarring of the lids However, it does occur in the aged as a part of the relaxation of the skin and the orbicularis oculi muscle. Atrophy may occur with ectropion as a part of an affection of the facial nerves, causing paralysis of the orbicularis oculi muscle, and under these circumstances the ectropion is known as the paralytic atrophic type. This affects only the lower lid

Trichiasis. Trichiasis is an inversion or ingrowing of eyelashes so that they rub against the cornea. This condition is manifested by congestion of the cornea, pain, lacrimation, photophobia, opacities, vascularization and ulceration. The most common cause of trichiasis is chronic trachoma.

Swelling, Puffiness. The eyelids, particularly the lower, are swollen in general anasarca, and are often the earliest seat of edema of renal origin. Anemia and hypoproteinemia may be attended by swelling of the lids. A bloated appearance of the eye, possibly with ecchymoses, is common in severe cough and pertussis. Angioneurotic edema and phenomena indicative of the allergic state may be seen in this locality. Edema of the lids and forehead which occasionally occurs in neurotic and adolescent individuals is often of allergic origin

Because of the anatomic connection between the blood vessels of the face and those of the cranial cavity, cerebral thrombosis may give rise to a swelling of one or both eyelids, with some protrusion of the eyeball, the puffiness subsequently extending to the face. Likewise infections of the face may extend through these same vessels and produce thrombosis of the cerebral venous sinuses.

Erysipelas and the stings of insects may be the cause of swelling so great as to prevent opening of the eye Severe coryza, hay fever, arsenic poisoning and iodism may induce noticeable swelling of the lids So, also, the lids are swollen in measles, variola, varicella and rickettsial infections, to mention only a few causes for swollen lids.

Hordeolum (Sty) A small, painful abscess at the edge of the eyelids is a sty or hordeolum When sties occur in successive series, it may be indicative of the overuse of defective eyes Small, single, and superficial sties are of purely local origin A sty is to be differentiated from chalazion (cyst of a meibomian gland), a slow-growing tumor which may become inflamed and suppurate.

A cystic swelling, of some duration, toward the inner canthus is a *mucocele* (chronic dacryocystitis), which may become inflamed and suppurate. After measles, scarlet fever, ophthalmia or other diseases in which there is conjunctival inflammation, there may be an acute inflammation of the lacrimal sac.

Ankyloblepharon. Ankyloblepharon is an adhesion of the margins of the upper and lower lids It may be either a congenital condition or due to burns. It may be partial or complete, and is often combined with symblepharon as a part of widespread scarring and deformities of the eyelids

Blepharophimosis. Blepharophimosis is a contraction of the palpebral fissure at the outer canthus. The outer angle is obscured by a vertical fold of skin from contraction following prolonged epiphora and blepharospasm.

Blepharospasm. Blepharospasm is characterized by an increased winking of the eyes Essential blepharospasm is the normal amount of winking of the eyes, both lids moving synchronously. Symptomatic blepharospasm may accompany disease of the eye as of the trigeminus nerve.

The term blepharospasm also may designate a slight narrowing of the palpebral aperture which may be of congenital origin or form ankyloblepharon.

Lagophthalmos. Lagophthalmos is a condition of incomplete closure of the palpebral aperture when the eyes are shut It may be due to narrowing of the lids from contraction of a scar, or to congenital deformity, ectropion, paralysis or loss of power of the orbicularis oculi, facial paralysis, or proptosis due to orbital tumor or

disease such as hyperthyroidism, hypothyroidism, paralysis agitans, encephalitis or diabetes.

There is a definite seasonal and periodic increase in head pain originating in the ocular muscles. Such headaches become more frequent in October, reach a peak in January and fall off in the spring. These headaches may be related to inactivity for when the days become longer and outdoor exercise is resumed, the incidence decreases.

The child who has a nervous breakdown or who is inattentive, the adult who has a headache at noon which is relieved by lunch and then has a recurrence at about 3 or 4 P.M., the student who cannot concentrate, and the convalescent patient who has headache may belong to the group of persons who have faulty, poor or inadequate ocular musculature. It is common to observe instability of eye musculature in patients undergoing a period of physical debility. Many of these patients who have ocular muscle imbalance are unaware of their difficulty.

Those who have hyperthyroidism, hypothyroidism and other glandular disturbances producing headaches often have been given a pair of glasses during the acute stage of the general disease. When recovery was attained, the tone of the ocular muscles improved and then the glasses were not suitable for them.

THE EYELIDS

The skin of the lids is thin and the subcutaneous tissue loose and devoid of fat. For these reasons after injury blood finds its way readily into the lids and shows plainly beneath the skin, as in the familiar black eye.

Mongoloid Fold. The mongoloid fold occurs commonly among Mongolians and occasionally among the whites.

The epicanthal fold among the Chinese, for instance, is, on the whole, much thicker than among white peoples. This condition of thickening in the Chinese eyelid is due to a characteristic disposition of the lower part of the orbicularis oculi muscle plate whereby, as seen in sagittal sections, the lower marginal fibers are disposed backward in a curve or even a kink.

Coloration of Skin of the Eyelids. A darkening or *duskiness* of the lids and under the eye is seen in some women and men. Duskiness in either men or women may be prominent in the anemia and pallor of brunet persons, or after fatigue, mental excitement, loss of sleep, or severe pain, and in exhausting diseases. Dark circles around or under the eyes are often hereditary and have no other significance. This condition is chiefly an affection of brunets who have thin fair skin.

One or more soft and very slightly elevated yellow patches seen on the upper eyelids of middle-aged women, or of elderly men or women, but most frequently in the soft tissue below the lower lids, are manifestations of xanthelasma. These spots or plaques, varying in size from 1 mm. to 1 cm. in diameter, when on the eyelid are situated near the inner angle, they may be either unilateral or bilateral. They may extend to, or primarily involve, the skin under the lower lid. These are of no diagnostic significance.

Coloboma of the lid is a triangular notching of the upper lid at the junction of its inner and middle thirds. Damage may be done to the eye if the deformity is not corrected.

Tophi. As in the ear, so may small nodules of sodium urate, significant of gout, form in the eyelids.

Entropion. Entropion is a rolling in of the margins of the eyelids and eyelashes. It is observed when there are scars or spasms of the lids. Cicatrical entropion most commonly affects the upper lid. Spastic entropion, which is due to spasm of the palpebral portion of the orbicularis oculi muscle, almost always affects the lower lid. These conditions are manifested by mechanical irritation and injury to the cornea from the turned-in eyelashes. There are congestion, pain, lacrimation and photophobia. If not corrected, opacity, vascularization and ulceration of the cornea ensue.

Carcinoma of the lid is usually a basal cell epithelioma, which is termed rodent ulcer. Malignant tumors of the eyelids occur in older people and more frequently on the margin of the lower than of the upper lid.

The tumor begins as a small elevation in the epithelium which ulcerates early and appears as an ulcer with indurated edges. The ulcer slowly spreads. Highly malignant squamous cell epithelioma occasionally occurs in young persons and spreads rapidly to the adjacent lymph nodes along the sides of the neck.

Sarcomas are rarely present on eyelids.

THE LACRIMAL APPARATUS

The lacrimal gland consists of two portions, an orbital or superior portion and a palpebral or inferior portion. The lacrimal gland opens by several fine ducts into the fornix of the conjunctiva.

The lacrimal canal, embracing the sac and the nasolacrimal duct, each about 12 mm in length, extends from just above the internal tarsal ligament or tendo oculi to the inferior meatus of the nose Below the palpebral ligament the sac is comparatively weak, and here it is that distention occurs and pus makes its exit

Dryness and Moisture of the Eye. The eye may become *dry* and *glazed* in prolonged fevers as well as in disease attended by lagophthalmos.

Lacrimation, an increased secretion of watery fluid, usually accompanies irritation or inflammation of the conjunctiva, and accordingly is present in measles, influenza, pertussis, and rickettsial infections in the early stages; in hay fever, asthma, coryza, trifacial neuralgia, facial paralysis and iodism, and when a foreign body is present in the eye The tears may overflow the edge of the lids (epiphora) because of displacement of the puncta lacrimalia or obstruction of the duct Cold winds and irritating vapors stimulate the flow of tears

Hyposecretion of lacrimal fluid is manifested by a feeling of dryness and burning, smarting sensation in the eyes, photophobia, and impairment of the vision Hyposecretion or deficiency in lacrimal secretion does result from extirpation of the lacrimal gland but is usually caused from the scarring of the conjunctiva that follows trachoma and xerophthalmia.

Stagnation of the contents of the lacrimal sac is quickly followed by infection and inflammation and is termed dacryocystitis. The lacrimal sac may become obstructed by either congenital causes or diseases of prenatal influences, or as a result of chronic nasal infection

Reduced production of lacrimal fluid is found in a condition known as keratoconjunctivitis sicca, often associated with defective secretion of the salivary gland and arthritis In vitamin A deficiency dry, greasy areas, known as Bitot's spots, may develop on the bulbar conjunctiva in the interpalpebral space

Epiphora is an overflow of tears and is a symptom in affections of the tear-conducting apparatus. The common causes of epiphora are exposure to wind or smoke, affections of the nose, and irritation of the retina by bright light It may also be dependent on increased secretion, which occurs in facial paralysis or from affections of the ophthalmic branch of the trigeminus nerve due to foreign bodies and inflammation of the eye Epiphora is commonest in old people, especially those who are exposed to the open air in cold weather, and often is without manifest lesions of the conjunctiva or tear passages

The ophthalmologist investigates the lacrimal passages by digital or instrumental pressure over the lacrimal sac and by injection of physiologic saline solution through the inferior punctum with the lacrimal syringe. If on pressure over the lacrimal sac a watery, viscid, mucopurulent discharge escapes through the punctum, it indicates an obstruction of the nasolacrimal duct. When obstruction is present, it may be situated in the nasolacrimal duct, or in the lacrimal sac, or at the junction of the common canaliculus with the lacrimal sac.

to exopthalmic goiter. In the last-named disease lagophthalmos is conjoined with protrusion of the eyeball (proptosis) and inability to follow with the upper lid a downward movement of the eyeball (von Graefe's sign) Lagophthalmos may be due to laxity of the tissues and absence of reflex blinking in patients who are extremely ill or moribund. Incomplete closure of the lids during sleep is commonly present in exhausting diseases. As the eyeballs are normally turned upward in sleeping, the scleras are thus exposed, giving a ghastly expression to the face. Owing to exposure the cornea becomes epidermoid (*xerosis corneae*) or keratosis sets in.

A similar rolling up of the eyes and imperfect closing of the lids are frequently seen in hysteria, in various convulsive disorders during the convulsion and immediately after death See ptosis (fall) of the upper lid, page 120.

Blepharitis. Blepharitis is characterized by reddened, thick, inflamed and crusted edges of the eyelids The edge of the lids may possibly be affected by minute ulcers or pustules The condition often results from an allergy, a previous ophthalmia or an attack of measles, or it may accompany anemia. Often, however, the cause is unknown.

Blepharitis is often the source of a chronic conjunctivitis. The etiology of the conjunctivitis may be suggested by the appearance of the blepharitis For instance, a mixed bacterial infection is often irregular in distribution and omits the meibomian glands and follicles of the cilia, whereas the staphylococcal variety involves these structures.

Residual swelling from recurrent sties indicates a residual staphylococcal infection of the lid margins which may be the source of a chronic conjunctivitis.

Meibomianitis is often present in conjunctivitis Expression of the contents of the meibomian glands and observation of the expressed material are regularly a part of the examination of the edges of the eyelids when disease is suspected. An inflammatory enlargement of one of the meibomian glands is termed *chalazion*

Swelling, redness and dilatation of lacrimal puncta are characteristic of streptomycotic concretions, which constitute an important cause of unilateral conjunctivitis. The diagnosis can be made by expressing material from the punctum and detecting the streptomyces on microscopic examination or on cultures

Molluscum contagiosum is a contagious disease caused by a filtrable virus The incubation period is variable, from 14 to 50 days It is transmitted by direct contact Man is the only known host The virus is cosmopolitan in distribution and affects all ages. The disease is characterized by the formation of firm, rounded, pearly white *skin nodules or tubercles varying in size from one to several millimeters in diameter* The lesions appear on the eyelids, the face, the scalp, arms, legs, buttocks, mucous membranes of the mouth and genitalia as single or multiple nodules. The soles and the palms are never affected These nodules usually present a central depression and contain semifluid caseous matter or solid matter made up of fat, epidermis and peculiar capsulated bodies, the molluscum corpuscles

Chronic edema of the eyelids due to blockage of lymph vessels is a characteristic feature of *lymphogranuloma inguinale keratoconjunctivitis* and can be considered almost pathognomonic of the infection

Herpes zoster ophthalmicus is an involvement of the eyelid when there is herpes zoster of the ophthalmic division of the fifth nerve The lid is affected by the characteristic lesions of herpes zoster The pain is severe The lesions heal, leaving scars which may be disfiguring

Tumors. *Papillomas* of the eyelids are common along the edges of the lids. They should be removed. Papillomas also include the verruca or wart Xanthelasma, naevus, hemangioma and lymphangioma may be present on the eyelids.

Small cysts having transparent contents are due to obstruction of the outlets of sweat glands, or keratomalacia, and are often seen on the borders of the eyelid. They give rise at times to irritation

which accompanies diphtheria; membranous conjunctivitis, however, may be non-diphtheritic. Meningitis may cause inflammation and discharge, perhaps unilateral, similar to that caused by the gonococcus.

Conjunctivitis may be a serious manifestation of tularemia (see Chapter 17).

The viral infections, for instance, acute coryza (head colds), influenza, measles, yellow fever and smallpox, often have conjunctival manifestations. The rickettsial diseases all affect the conjunctivae.

Purulent conjunctivitis, or ophthalmia neonatorum, is usually caused by the gonococcus. This is an extremely severe form of conjunctivitis and in the newborn child is a potent cause of blindness if not immediately treated by silver nitrate drops in the eyes

Gonorrheal conjunctivitis in the adult is acquired by direct transfer of material infected with gonococci to the eye. The usual method of transfer is by the hands from the genitals The unusual transfers occur from the use of soiled towels or spattering of pus containing the organisms. The incubation period is from a few hours to 2 or 3 days

The disease varies in severity. In the virulent infections the eyelids may begin to swell and within a few hours become so tense that they cannot be opened. In all there is a rapidly developing chemosis. The lids and fornix of the affected eye are swollen, tense and covered with a profuse purulent secretion. In severe infections there may be only a blood-tinged discharge. In a few days the symptoms begin to subside but the eye continues to discharge pus for 2 to 3 weeks. The course as well as the disease has changed greatly since the advent of chemotherapy and antibiotic therapy

Untreated or inadequately treated gonorrheal conjunctivitis often injures the cornea—corneal ulceration. Ulceration is followed by cicatrization, staphyloma and sometimes a panophthalmitis

The diagnosis of gonorrheal conjunctivitis is usually obvious from the history One eye alone is affected. In the mild forms of the disease the diagnosis may be difficult because of resemblance of the disease to other forms of acute bacterial conjunctivitis and viral conjunctivitis, particularly swimming-pool or inclusion conjunctivitis The diagnosis is made from positive smears and cultures

The subjective symptoms of acute conjunctivitis are itching and smarting sensations, usually referred to the eyelids These sensations become progressively more intense and the lids feel hot and heavy as though sand or foreign bodies were underneath the lids There is a varying amount of photophobia Owing to altered secretions on the cornea, there may be blurring of the vision. The symptoms are usually worse toward evening than during the rest of the day The affection may be limited to one eye, but usually both eyes are implicated; either from the start, or within a very few days after the first eye is affected, the other will become involved.

All types of infectious conjunctivitis are characterized by the brilliant red color of the conjunctiva due to hyperemia and formation of new vessels When the upper lid alone is reddened, the possible presence of a foreign body is a first consideration.

The various types of *allergic conjunctivitis* are common and can often be distinguished by the character of the conjunctival secretions. The secretion from allergic conjunctivitis, particularly vernal catarrh, has a high fibrin content and is stringy in character in contrast to the flaky or amorphous exudate of an ordinary bacterial infection.

drops. Full or excessive doses of many drugs such as arsenic, potassium iodide and sulfonamides, especially if there is an idiosyncrasy, cause chemosis.

Obstruction of the *nasolacrimal ducts* may be due to prenatal influence or may be the result of chronic nasal infection, trauma or ulceration, or may occur idiopathically Obstruction of the nasolacrimal ducts is manifested by epiphora at all times but is greatly increased by exposure to cold, wind, dust or smoke.

Acute inflammation of the lacrimal gland is a rare condition. The gland is sometimes enlarged in mumps or epidemic parotitis. A bilateral enlargement of the lacrimal glands is rare *Dacryocystitis,* infection of the lacrimal system, may become chronic and produce a form of chronic conjunctivitis affecting chiefly the upper lid Occasionally a blepharitis accompanies these conditions. Acute exacerbations of a chronic form of dacryocystitis may be manifested by acute swelling and obstruction resulting in abscess formation in the lacrimal sac

In *eversion of the puncta* the lower punctum looks forward and away from the depression where the tears accumulate and thus epiphora results. Eversion of the punctum and the canaliculus may be of congenital origin or it may be caused by scarring from wounds or by chronic inflammation. This condition most commonly occurs in old age or in facial palsy, conjunctivitis, blepharitis or ectropion The canaliculus may contain a cilium or concretions which irregularly obstruct the passages and produce a swelling of the tissue at the inner canthus of the eye

Malignant tumors of the lacrimal ducts and glands of the eye occur and these are usually sarcoma These tumors are classed with orbital tumors The most frequent orbital tumors are those that extend into the orbit from the adjacent structures, usually from the meninges or the brain They may extend from the zygomatic and temporal fossae or from the nasal cavities When such infiltrations occur, the eye is protruded and dry.

Dermoid tumors arising from remnants of the orbital crest occur at the outer or inner angles of the eyes, more frequently at the outer angles Dermoid tumors are to be differentiated from meningoceles

THE CONJUNCTIVA

The conjunctiva lines the eyelids (palpebral conjunctiva) and covers the eyeball (bulbar or ocular conjunctiva) in front.

A *symblepharon* is a cicatricial attachment between the conjunctiva of the lid and the eyeball It is usually caused by an injury.

A *pterygium* is a triangular fold of membrane occupying the interpalpebral fissure extending from the inner or outer part of the ocular conjunctiva to the cornea. This condition occurs usually in elderly people who have lived in the wind and dust of the plains or deserts

Subconjunctival hemorrhage or ecchymosis often occurs without assignable cause. Occurring after an injury, either form of bleeding may indicate a fracture of the base of the skull anteriorly, the blood passing forward into the orbit The other causes are the violent straining which may occur in severe coughing, severe vomiting, straining at the time of bowel movements and heavy lifting. *Subconjunctival ecchymoses* may also occur during a convulsive seizure and in asthma or severe dyspnea. They may be hemorrhagic infarcts and significant of septicemia or septicopyemia

Conjunctivitis or inflammation of the conjunctiva is common and often is caused by the presence of foreign bodies in the eye or by exposure to wind, either hot or cold, and to dust or pollens, smoke or intense light.

The infectious forms of conjunctivitis due to bacteria may be acquired from [illegible] Epi-
[illegible] ies
[illegible] ac-
terial origin, is often known as *pink-eye* and is likely to occur during the spring or fall months (vernal conjunctivitis). Conjunctivitis may be of the membranous type

the lower lid. On re-

tivitis the *second eye* becomes involved after a varying period of time. As a rule, the course of the disease in the second eye is much shorter and the inflammation considerably less than in the first eye.

Systemic manifestations are headache and night pain, fever and malaise which may occur with involvement of the one or the second eye. Corneal involvement is a frequent and serious complication, and this may occur without any signs of pain or photophobia or other subjective or objective symptoms. The intensity and sequence of appearance of the symptoms therefore have no bearing on the duration or intensity of the disease. Often eyes which show violent symptoms in the beginning may clear up rapidly and without resultant visual impairment. The time interval between the onset of the disease and the involvement of the cornea varies from 1 to 5 weeks. Usually the first sign of corneal involvement is the appearance of several tiny punctate infiltrates of the cornea in the subepithelial layer The corneal epithelium remains intact and does not stain with fluorescein In the majority of cases the corneal infiltrates are on the exposed part of the cornea, that is, within the confines of the palpebral fissure, and usually in the pupillary area.

The diagnosis of epidemic keratoconjunctivitis depends on the presence of an acute keratoconjunctivitis with practically no discharge from the conjunctiva. This stage is followed by an acute swelling of the preauricular nodes and in some there is also swelling of the submaxillary and cervical nodes.

Herpetic Keratoconjunctivitis. The clinical characteristics which should arouse suspicion of an herpetic etiology in any inflammatory condition of the eye were outlined by Maumenee, Hayes and Hartman as follows: (1) the frequency with which it follows pyrexia; (2) relapses or recurrences; (3) slight, if any, purulent discharges; (4) herpetic vesicles on the lids; (5) bacteriologic sterility of the conjunctiva, (6) rapid and complete healing as a rule, (7) hypesthesia of the eye, (8) a visible and slightly tender preauricular node Many of these clinical manifestations can be caused by the virus of epidemic keratoconjunctivitis

Inclusion Conjunctivitis (*Paratrachoma or Swimming Pool Conjunctivitis*) This disease is caused by a virus of large particulate size belonging to the psittacosis-lymphogranuloma venereum group of organisms The conjunctivae are increased greatly in thickness and contain numerous basophilic cytoplasmic inclusion bodies which are morphologically identical with those of trachoma. The disease occurs in infants and in adults

The incubation period is from 5 to 12 days In the infant the disease develops rapidly, particularly in the lower lid, and pseudomembranes may develop rapidly. After 10 to 15 days the disease decreases in intensity, but it lasts for months or for a year

In the adult the disease develops as a follicular conjunctivitis with scanty discharge and periauricular adenopathy. As in the disease in infants, the lower lid is more severely involved than the upper lid The disease in the adult is more chronic than that seen in the infant

The diagnosis of inclusion conjunctivitis in the infant is made most easily by remembering that this conjunctivitis is likely to commence 5 to 12 days after birth, whereas gonorrheal conjunctivitis begins very soon after birth The lower fornix has a coxcomb-like appearance, and inclusion bodies can be demonstrated. Trachoma never occurs in the newborn child.

In the adult, diagnostically significant is the presence of inclusion bodies from the lower lid in a patient who does not have pannus or significant conjunctival cicatrization The follicular hypertrophy is much more definite in the lower lid than in the upper.

Ulcers of the cornea are attended with reddening of the eye. Characteristically, glaucoma may cause reddening of the conjunctivae.

Facial paralysis, by causing undue exposure of the eyeball or a neuralgia of the fifth nerve, may give rise to redness and inflammation

Follicles are not visible on the normal tarsal conjunctiva. When follicles are visible, they have hypertrophied. The significance of *follicular hypertrophy* depends primarily on location and secondarily on their prominence. Follicles involving the upper tarsal conjunctiva are suggestive of trachoma When the upper tarsal conjunctiva is clear and follicles in other parts of the conjunctivae are affected the diagnosis usually is follicular conjunctivitis. The follicles of trachoma are soft, gelatinous and easily expressed, while the follicles of follicular conjunctivitis are hard and expressible only with difficulty

In a true *membranous conjunctivitis*, coagulation of the fibrinous exudate has occurred so that removal of the membrane leaves a bleeding, rough surface. Conjunctival *pseudomembranes* are of two types, the fine, transient type and the thick, relatively permanent type An example of a fine, transparent membrane occurs in vernal catarrh, acute conjunctivitis such as gonococcal conjunctivitis and epidemic keratoconjunctivitis

Thick, opaque, pseudomembranes occur in diphtheria, in streptococcal infections, in erythema multiforme, and occasionally in ocular pemphigus

Conjunctival ulceration is characteristic of conjunctival tuberculosis and oculoglandular tularemia, chancre of the conjunctiva and acute pemphigus The ulcers of acute pemphigus are readily distinguished from other ulcers by their shallow character and transient nature

The conjunctival *phlyctenule* or an elevated nodule or an ulcer of the corneal conjunctiva is pathognomonic of phlyctenular conjunctivitis and is believed to be an allergic reaction to a bacterial antigen, commonly tuberculoprotein Unlike conjunctival phlyctenules, corneal phlyctenules lack diagnostic value

Conjunctival granulomas are associated with buried foreign bodies or ruptured chalazia, conjunctival tuberculosis and oculoglandular tularemia The conjunctivae in leptothrichosis have small, whitish or grayish necrotic foci without gross ulceration A single large granuloma without diffuse conjunctival inflammation is suggestive of rhinosporidiosis

Conjunctival concretions indicate the occurrence of past or present chronic conjunctivitis Their diagnostic value is slight, but when they occur in large numbers *they can be considered suggestive of an old trachoma*

Conjunctival *scars* follow injury, operation for chalazia or burns, trachoma, pemphigus, diphtheria and irradiation The scars of trachoma involve the upper tarsal conjunctiva predominantly and those of ocular pemphigus the lower tarsal conjunctiva and fornix Ocular pemphigus may cause an obliteration of the entire lower fornix, a condition which distinguishes it from trachoma

The term *superficial punctate keratitis* is a descriptive name of epidemic keratoconjunctivitis, and it is often employed as a general morphologic term for the designation of any condition presenting multiple, small, discrete lesions of the cornea affecting the epithelial and immediately adjacent subepithelial tissues.

Epidemic Keratoconjunctivitis. This is a disease of viral origin There is evidence to indicate a close immunologic relationship between the viruses of epidemic keratoconjunctivitis and St Louis, Japanese and West Nile encephalitis viruses.

The earliest symptoms vary greatly in intensity. They commence with a sandy feeling, redness and swelling of the palpebral conjunctiva of *one eye*. At this stage it may be thought that there is a foreign body present causing tearing of the eye. After 12 to 36 hours the bulbar conjunctiva too becomes congested and hyperemic, and varying degrees of edema of the lids (particularly of the upper lid) ensue Occasionally the amount of edema is extreme and it may be difficult to open the eyes

be present along the lower retrotarsal fold without any evidence of inflammation, and as such the condition is known as *folliculosis*

THE CORNEA

The cornea is the transparent portion of the external coat of the eyeball, the anterior extension of the sclera The cornea consists of four layers. (1) the corneal epithelium, which is continuous with that of the conjunctiva; (2) the substantia propria; (3) the posterior elastic lamina and (4) the endothelium of the anterior chamber of the eye. The last three layers anteriorly are continuous with similar tissues of the sclera However, in the sclera there is not the definite arrangement of tissues as in the cornea. In contrast to the cornea, the outer surface of the sclera is bluish white and nontransparent.

Diseases of the Cornea. Many of the inflammatory diseases of the cornea have been discussed in connection with inflammation of the conjunctiva, which is continued over the cornea Injuries of the cornea have been included with other injuries of the anterior part of the eye.

Ulcers. A reddened, painful, photophobic eye, with a clear cornea, except for a loss of substance at one point, is an example of a corneal ulcer. Corneal ulcerations often result from scratches or foreign bodies, conjunctivitis and burns of the eyes. Exophthalmos, unilateral from a tumor of the orbit, or as a progressive condition of unknown cause, but usually associated with exophthalmic goiter, may be the cause of corneal ulceration The ulcerations in exophthalmic goiter, and also in some cases of facial paralysis, may be due to the constant exposure of the eye consequent on the inability of the lids to cover the protruding eyeballs.

The unilateral inflammation of the eye in meningitis may lead to a corneal ulcer. In disease of the first division of the fifth nerve, for instance herpes zoster with or without resulting anesthesia of the cornea and conjunctiva, the cornea may undergo ulceration, occasionally intractable.

Hypopyon is a collection of pus in the anterior chamber of the eye, which may accompany corneal ulceration. The pus is derived, not from the corneal ulcers, but from an exudation from the iris and the ciliary body when these parts participate in the inflammation

Opacities of the Cornea. Opacities of the cornea are usually caused by corneal ulceration or involvement of the cornea by inflammation or ulceration as the result of an injury. An opacity of the cornea will reduce vision when it encroaches on the pupillary area Over the pupillary area a very slight opacity may cause much visual disturbance on account of the resulting diffusion and irregular refraction of light A linear or a nebular form of opacity will cause a great deal more visual disturbance than a circumscribed opacity Dense opacities or deformities of the cornea may cause a disfigurement of the eye as well as interfere with its vision

Interstitial or deep keratitis is characterized by a cellular infiltration of the deep layers of the cornea without ulceration during any stage of its existence There is involvement of the uvea which accounts for many of the symptoms

In many instances the disease is due to *congenital syphilis* It affects girls and boys alike and becomes manifest between the ages of 5 and 15 years In rare instances the patient may be older

During the early stages of congenital lues there are successive periods of photophobia, lacrimation, pain, and interference with vision in both eyes In some instances the symptoms subside and the eye clears up entirely or nearly so

In the beginning, there is present a patch of grayish infiltration which may be situated in any part of the cornea The patch enlarges to involve the entire front of the eye The cornea becomes softened The blood vessels begin to appear over the periphery of the dull gray-appearing cornea, giving the limbus a reddened color. Vision may be reduced to light perception only. However, improvement will usually take place eventually.

In both infants and adults the disease resolves without residual conjunctival or corneal changes

Trachoma. Trachoma is caused by a filtrable virus. The virus of trachoma is *distinctive from most other viruses, since it seems to be susceptible to chemotherapy,* to originate basophilic intrusion bodies and to have an intercellular cycle of morphologic variation For these and other reasons it has been suggested that trachoma and inclusion conjunctivitis should be classified with the rickettsial diseases. An objection to such a classification is that trachoma is not transmitted by an arthropod host.

Trachoma is a highly contagious disease, which is responsible for much partial or total blindness. The disease may present few or no symptoms. The onset of the disease usually is with a mild conjunctivitis with thickening, edema, and congestion of the conjunctivae In some patients there are photophobia, blepharospasm, lacrimation, itching, burning, and painful sensations accompanied by visual disturbances.

On examination in the early stages of the disease there may be found minute follicles which can be seen in the upper tarsal conjunctiva On microscopic examination of the scrapings from these follicles, the characteristic inclusion bodies may be found At this stage it is difficult to differentiate trachoma from inclusion conjunctivitis or gonorrheal conjunctivitis As the disease progresses, there is papillary hypertrophy of the tarsal conjunctiva, especially of the upper lid, which imparts to the lid the characteristic granular appearance With further progression the papillae may increase in size, and there appears a diffuse infiltration of the conjunctiva, which is studded with grayish, rounded, translucent follicles arranged in parallel rows. The trachomatous pannus consists of loops of blood vessels extending into the cornea between the epithelium and Bowman's membrane, these loops are caused by a stopping or cutting off of the blood vessels by scarring The cornea presents a cloudy appearance and may be gray and translucent. Its surface becomes vascularized, the blood vessels stringing from the conjunctival vessels at the limbus. This process advances until it covers the upper half of the cornea In severe cases it may cover the entire cornea and thus vision and perception of light are reduced and the patient loses his eyesight

From this stage of development of trachoma the disease may continue to progress, or complete retrogression may take place, so that the cornea again becomes *transparent The final visual condition depends on the extent of corneal opacification* and unevenness In severe instances of the disease iritis develops which is due to a change similar to those which occur in the conjunctivae Superficial corneal ulcers may appear near the margin of the advancing iritic pannus Ptosis may develop and become permanent

Trachoma, after months or years, reaches the stage at which formation of scar tissue is the predominating process As scar tissue forms, the papillae and the follicles disappear In the tarsal conjunctiva there may have formed narrow bands of white scars which parallel the lid margin In general, trachoma heals by the formation of scar tissue Consequently the sequelae are as follows. ectropion, entropion, *or trichiasis Often the movements of the eyeballs are restricted,* iritic pannus may be present, and corneal opacities may result from the corneal ulcers. Staphyloma of the cornea may follow a perforation of a corneal ulcer A dry, scaly state of the conjunctiva may be a sequela of severe trachoma

The diagnosis is made from the prolonged course and on the basis of the clinical examination and the finding of characteristic minute inclusion bodies in the cytoplasm of epithelial cells in scrapings from the conjunctiva

Chronic Conjunctivitis. Any of the acute forms of conjunctivitis may be followed by chronic conjunctivitis, the symptoms of which are essentially a prolongation of an acute form of the disease *Follicular conjunctivitis* is a form characterized by the occurrence of lymph follicles distributed along the lower retrotarsal fold. They appear as small, round, oval, pinkish bodies arranged in rows These follicles may

mortar or whitewash, strong acids and alkalies endanger the eye by injuring the cornea and producing symblepharon. Strong ammonia is particularly harmful, causing necrosis of the cornea; hydrochloric acid much less so. The central core of golf balls often contains caustics such as barium sulfate or sodium hydroxide which spurt into the eye if the ball is slit open

Ensuing immediately on the introduction of a caustic into the eye are intense conjunctivitis and chemosis, but the cornea looks clear; in this stage it is difficult to be certain of the extent of the injury. A drop of fluorescein solution in the eye will reveal on magnification the extent of the area denuded of epithelium. Therefore the patient is urged to secure the services of an ophthalmologist until the gravity of the injury can be determined. In severe injuries the cornea is dull or opaque. In the succeeding days an eschar forms and is thrown off This is followed by granulation of the injured conjunctiva and frequently by ulceration of the cornea. In severe burns the foregoing process may cause the whole cornea to be destroyed; perforation takes place, and the eye shrinks In less severe burns a dense milky white opacity forms, porcelain-like in lime burns, and sight is lost There is little danger of the loss of sight in the less severe injuries but the conjunctiva may form adhesions of the lid to the globe Adhesions are most likely to occur with the lower lid, the caustic acting principally on the lower fornix, which is obliterated by organization of the granulation tissue. The symblepharon thus produced impedes the movements of the globe and may even interfere with its nutrition

THE ORBIT

Pain In and Around the Eye. Foreign bodies and inflammatory diseases of the iris or conjunctiva are common causes of a painful eye. Pain in and around the eye is frequently due to trigeminal neuralgia or to migraine. Before treatment is given, these conditions should be differentiated from acute glaucoma to avoid error in therapy The presence of dimmed vision, reddened eye, hazy cornea, dilated pupil and greatly increased tension, perhaps with nausea and vomiting, will declare the case to be one of glaucoma.

Photophobia is a form of eye pain excited by exposure to light. It is present to varying degrees in the conjunctivitis of measles, influenza, the early stage of pertussis and severe coryza, or the formation of the vesicles of variola and varicella on the cornea Ocular or retinal hyperesthesia is a rare form of photophobia not dependent on local inflammatory disease of the eye, and it is usually, although not always, due to functional disturbance of the optic tract and nerve or the cortical centers for vision It is a frequent *symptom in neurasthenia, hysteria, migraine and*, at times, the hypnotic state. It may be present in cinchonism, in the early stages of [illegible]

[illegible]

[illegible] the orbital tissues (panophthalmia).

Suppuration of the orbit may originate extrinsically and extend into it as from erysipelas, from caries of the orbital bones or adjacent structures or in syphilis. If pus enters the orbit, it is usually from suppuration of the frontal sinus and ethmoidal cells. If so, the swelling presents at the upper portion of the inner angle of the eye. Pus in the maxillary sinus usually discharges into the nose. Pus within the orbit [illegible]

[illegible]

[illegible] orbital tumors, however, arise extrinsic to the orbit and enter through its natural openings or extend directly through its bony walls. Tumors arriving in the orbit through natural openings may enter (1) from the brain through the optic foramen or sphenoidal fissure, (2) from the region of the zygomatic and temporal fossae

In some instances all of the signs of the disease disappear. In others, when there is severe involvement of the iris, choroid and vitreous, sight may be lost or there may remain a permanent opacity in the cornea.

The diagnosis of interstitial keratitis of syphilitic origin is based on the history The physical examination often reveals the presence of Hutchinson's teeth, scars at the angles of the mouth where rhagades have healed, and head deformities. The head deformities consist of a square forehead and prominent frontal eminences Often there are enlarged lymph nodes in the posterior triangles of the neck. There may be visible tibial deformities. The roentgenographic examination of the bones may reveal irregular cortical outlines.

The classic triad for the diagnosis of congenital syphilis is (1) interstitial keratitis, (2) Hutchinson's teeth and (3) deafness (labyrinthine disease).

Arcus Senilis. This is a degenerative condition of the cornea. The true arcus is an ill-defined, grayish, partial or complete ring at the circumference of the cornea, the cornea itself being somewhat hazy It was formerly wrongly considered to be an indication of beginning arteriosclerosis and the degeneration of old age. The false arcus is a sharply delineated ring of a clear yellow or yellowish white color, due to a deposit of fat Neither one is of diagnostic significance.

INJURIES TO THE ANTERIOR STRUCTURES OF THE EYE FROM FOREIGN BODIES AND PHYSICAL AGENTS

The eye is subject to injury from foreign bodies, burns, the action of caustics, contusions, wounds and radiant energy

Foreign Bodies. Foreign bodies on the conjunctiva or on the cornea cause sudden discomfort and blepharospasm The foreign body may adhere to the palpebral conjunctiva, or it is likely to be dragged across the cornea, which it excoriates. It may be floated by tears toward the inner canthus and pass into the nasal duct. Very frequently it becomes lodged at about the middle of the upper sulcus subtarsalis, where it is likely to irritate the cornea, or in the upper fornix. When it adheres to the bulbar conjunctiva, it may lodge there Foreign bodies are generally imbedded in a mass of granulation tissue The chitin of insects and the husks of seeds may adhere to the cornea, usually at the limbus, for several days or even weeks or until the inflammatory reaction is sufficient to dislodge them

Particles of steel and emery are likely to penetrate the epithelium or substantia propria. Larger particles of steel, stone or glass may perforate the globe. When situated in the cornea, they cause great pain and irritation The pupil is often constricted If allowed to remain, they expose the cornea to the dangers of infection by organisms in the conjunctival sac and ulceration This may lead to a small superficial slough being cast off, carrying the foreign body with it The small ulcer thus formed may heal, but if virulent organisms are present, a spreading ulcer, with or without hypopyon, may develop

Foreign bodies are probably more frequent in the lower cul-de-sac than in the upper, but in the former location they may be removed by the lacrimal fluid or by the patient's own efforts The upper cul-de-sac requires more scrutiny than does the lower, for it extends several millimeters above the tarsus in the upper lid, and simple eversion of the upper lid may not expose it. When a foreign body is suspected but remains undetected, the tarsus should be everted and then the cul-de-sac stretched forward and convexly with a lid everter The fold behind the lacrimal caruncle is another recess which may conceal a foreign body.

Intra-ocular foreign bodies are suspected in blast injuries, or when the patient has been near the application of striking, grinding or cutting force applied to metal.

Burns and Injuries by Caustics. Burns by hot water, steam, hot ashes, exploding powder or molten metal, and injuries by caustics such as lime, usually from fresh

if toward the nose, the strabismus is convergent or internal. Vertical squint may be upward or downward. By asking the patient to look at the tip of the examiner's finger, it is usually easy to decide which eye squints and whether the squint is convergent, divergent, upward, or downward If the strabismus is slight and uncertainty arises, the finger should be held directly in front of the face, about 18 inches (46 cm) distant, and the patient asked to gaze at it The apparently normal eye should then be covered by a card. The uncovered eye, if it be the squinting one, will immediately alter its position so as to fix itself on the finger, thus demonstrating that it had not before been properly directed.

Strabismus, with reference to its origin, may be of two kinds, concomitant and paralytic.

In *concomitant strabismus* the squinting eye will retain its mobility, moving readily in every direction concomitantly with its companion, the degree of strabismus remaining substantially the same. The principal causes of concomitant strabismus are overaction of certain muscles consequent on refractive errors, and imperfect vision of an eye, with resulting weakness of the muscles.

In *paralytic strabismus* the squinting eye loses some of its power of movement, owing to a loss of power in one or more of the external ocular muscles. Closely connected with and dependent on paralysis of the ocular muscles and strabismus is the subjective symptom of diplopia.

DIPLOPIA. Double vision depends on the fact that unless the visual axes are correctly adjusted, each to the other, the images of the objects do not fall on identical points in the retinas. Under normal conditions each image falls on the macula lutea of each retina, combining to form a single image in the sensorium

Aside from the double vision which is produced by the action of alcohol, atropine and other drugs on the ocular nerves, diplopia, like strabismus, is a symptom of paralysis of the ocular muscles Any lesion of the brain, spinal cord or basal meninges which causes paralysis of one or more of the external ocular muscles may be attended with diplopia.

Double sight with one eye may occur in cataract and astigmatism, owing to irregular refraction, and in brain tumor as a psychic aberration

CONJUGATE DEVIATION. If both eyes are turned strongly and persistently toward one side, either right or left, the condition is termed conjugate deviation This condition may be due to either spasm or paralysis of the internal rectus of one side and the external rectus of the other side, and the eyes may be turned toward the lesion or away from it, depending on its location and whether it is irritative or destructive This symptom depends on the normally associated action of the internal rectus of one side and the external rectus of the other in effecting horizontal co-ordinated motion of both eyes to the right or left

The lesions producing conjugate deviation are, in particular, cerebral hemorrhage, thrombosis, tumors and meningitis Often, if the lesion is a left-sided one and causes right hemiplegia, the eyes look toward the lesion, but it is said that if the lesion is irritant or becomes so and spasms or convulsions occur, the eyes turn away from the lesion

The determination of the nature of the lesion must be made by study of the associated symptoms of brain tumor, meningitis, apoplexy, sclerosis or abscess.

NYSTAGMUS. This is a rapid involuntary oscillation or slow movement of both eyeballs, usually from side to side (lateral nystagmus), sometimes vertical or rotary. It is a clonic bilateral spasm of the ocular muscles due to some irritation, either functional or organic, affecting the ocular muscle centers. If nystagmus is very slight, it may be intensified by directing the patient to look steadily at an object held well to one side or the other, or if the nystagmus is vertical or rotary, by directing the eye upward or downward, or circumducting the eye by moving the object

Nystagmus is present in many cases of blindness or defective sight caused by

through the sphenomaxillary fissure or (3) from the nasal cavities through the nasolacrimal duct.

Tumors which arrive in the orbit by penetrating its walls may come (1) from the nasal cavities and ethmoidal cells, pushing through the thin internal wall; (2) from the frontal sinus, appearing at the upper inner angle; (3) from the sphenoidal cells at the posterior portion of the inner wall; (4) from the brain cavity above, breaking through the roof, or (5) from the maxillary sinus below, pushing through the floor.

Dermoids and Meningoceles. In the fetus the frontonasal process extends to join the maxillary processes on each side This leaves an orbitonasal cleft to form the orbit Owing to defects in the development of this cleft, dermoid tumors may occur in its course They are seen at either the outer or the inner angle of the eye They are commoner at the outer angle near the external angular process than at the inner angle, and may have a prolongation to the dura mater They also occur at the inner angle at the frontonasal suture. At this point, also, meningoceles are likely to occur

Symptoms Indicative of Disturbances of the Ocular Muscles. PTOSIS Drooping of the upper eyelid, with inability to raise it (ptosis), may exist alone, but it may be combined with paralysis of the third nerve Ptosis is usually due to paralysis of the levator palpebrae As the levator palpebrae is innervated by the second portion of the oculomotor nucleus, ptosis is dependent on some interference with the function of the third nerve, its nucleus, or its cortical center

Ptosis may be congenital and hereditary, unilateral or bilateral, partial or complete In complete ptosis the lid drops enough to interfere with vision. The attempts made to counteract this interference with vision consist of throwing the head back and raising the eyebrows by forced contraction of the frontalis muscle Instances of partial ptosis may be masked by these compensatory mechanisms Detection of partial ptosis is accomplished by asking the patient to look upward while the eyelashes are pressed firmly against the inferior bony margin of the orbit

Berke classified congenital ptosis in accordance with the muscles or structures involved, separating them according to whether the superior rectus muscles are involved alone or there is weakness of the superior rectus and the inferior oblique muscles combined In addition to involvement of the recti and inferior oblique muscles attention is paid to ptosis associated with the jaw-winking phenomenon and, finally, to ptosis that may be associated with blepharophimosis Congenital ptosis is most frequently unilateral This classification of congenital ptosis is useful, since it is helpful in selecting the proper surgical procedure if any is to be employed

Acquired ptosis is usually unilateral It may be part of the symptom complex of paresis or paralysis of the whole of the third nerve, or may be due to paresis or paralysis of the branch supplying the levator Isolated ptosis without other signs of oculomotor paralysis may result from disease of the brain (cerebral ptosis) Acquired ptosis may be due to direct injury of the muscle or its nerve supply, deformity and increased weight of the lid brought about by edema, trachoma, and tumors. In inflammatory necrotic processes and during marasmus with tissue loss the lid may sag from lack of support Bilateral ptosis may occur as a part of the syndrome of myasthenia gravis In severe neuralgia of the fifth nerve in tetanus, in autonomic nerve lesions and in hysteria, ptosis may coexist

The amount of ptosis sometimes alters with the position of the globe, attaining its highest pitch in abduction of the eye, its least in adduction. In all forms of ptosis there may be a synkinesis of movement, the lid rises when the jaw is moved, as in mastication, though it remains immobile when an attempt is made to look upward

STRABISMUS. Squint or strabismus is inability to bring the visual axis of both eyes to bear at the same instant on one point, the visual axis of one eye constantly deviating, as a rule horizontally, sometimes vertically, from the object inspected If the squinting eye turns toward the temple, the strabismus is divergent or external;

lid from paralysis of the levator palpebrae, and dilatation of the pupil and paralysis of the accommodations of the eye If the sixth or abducens nerve is paralyzed, the eye cannot be turned outward. If the fourth or patheticus nerve is paralyzed, the superior oblique muscle fails to act, and the double vision produced is worse when the patient looks down because the superior oblique is normally a depressor muscle. The lacrimal, frontal and nasal branches of the fifth nerve are nerves of sensation, hence in supraorbital neuralgia and that affecting the nasal branch, pain is felt in the orbit at the inner angle of the eye and down the side of the nose

Ocular Paralysis. Paralysis of the ocular muscles is termed ophthalmoplegia. In testing the ocular muscles for evidence of paralysis or weakness ask the patient to follow the finger moved in different directions. Evidences of weakness or paralysis may thus be detected when there is inability of the eye to follow the moving finger If a more careful investigation is needed, as with the slighter degrees of paralysis and the ocular asthenopias, the patient should be referred to a competent ophthalmologist.

Paralysis of the Third Nerve. If there are ptosis, slight exophthalmos, external strabismus, diplopia, and a dilated pupil which reacts neither to light nor to accommodation, and if when an object is moved in various directions the eye fails to follow it upward, inward, or far downward, but will move outward and a little downward by means of the external rectus and superior oblique, there is complete oculomotor paralysis. In many cases some of the muscles escape, the levator and rectus superior or the iris and the ciliary muscle being alone affected, or ptosis may exist, with a dilated pupil

The most frequent causes of oculomotor paralysis are exposure to cold and to syphilis, the latter giving rise to a basal meningitis or a gummatous growth involving the roots of the nerve Various forms and degrees of oculomotor paralysis are significant symptoms in cases of encephalitis and botulism

Partial paralysis may be due to a cortical lesion affecting the inferior parietal lobule. Undue exposure to light, migraine, and the excessive use of alcohol or morphine may cause temporary paralysis

As organic disease of the third-nerve nucleus is usually associated with disease of the fourth and sixth nuclei, an oculomotor paralysis, without loss of power of the external rectus and superior oblique, is, as a rule, functional.

While the nerve is penetrating the crus it may be involved by tumor or other lesion of the crus, in which case there will be partial or complete third-nerve paralysis conjoined with hemiplegia on the opposite side of the body, a combination characteristic of unilateral disease of the crus If in addition there are unilateral paralysis and atrophy of the tongue, the lesion is localized in the inner and inferior aspect of the crus involving the cerebral fibers passing to the nucleus of the hypoglossal or motor nerve of the tongue.

Ptosis occurring on one side, disappearing and then appearing on the other side (alternating), may be due to variable lesions in the neighborhood of the nucleus.

At and after its emergence from the pons on its way to the sphenoidal fissure, the third nerve may be involved by basilar meningitis or tumors

The lesions of locomotor ataxia which cause ptosis may be in the same locality. If due to disease at the base, the oculomotor paralysis is usually bilateral and likely to be accompanied by interference with the function of the other cranial nerves Third-nerve paralysis may also be one of the symptoms of primary muscular atrophy and upper bulbar palsy

Oculomotor paralysis may be indicative of pressure in the cavernous sinus or inflammation at the sphenoidal fissure, or injury (fracture) in either locality

Loss of accommodation, loss of light reflex, and external squint following an attack of diphtheria are usually indicative of a neuritis of the third nerve

Paralysis of the Fourth Nerve. The fourth nerve supplies the superior oblique muscle, and paralysis of this muscle is somewhat difficult of detection If paralyzed, when the fixing object is moved downward below the horizontal line the diseased eye fails to follow it, there is slight convergent strabismus, and the patient has double vision while looking down.

optic atrophy, amaurosis, and corneal opacities. It may be found in albinos. It is frequently seen in epileptic or other convulsions, and may form a part of the symptomatology of neurasthenia, hysteria, chorea and, in some cases, of multiple sclerosis and insanity

The most important diagnostic associations of nystagmus, however, are with Friedreich's ataxia, disseminated (insular) multiple sclerosis, and brain tumor, especially growths involving the cerebellum, pons or crus Acute basal meningitis is likely to present nystagmus.

A special variety of nystagmus may be inherited. It resembles in appearance the ocular type, yet it is not associated with defective vision. The movements of the eyes are constant, horizontal and pendular, of small range on forward gaze and of increasing amplitude on gaze to the sides. The rate is about 120 per minute. In most cases it is noted by the mother when the child is a few weeks to a few months of age.

This type of nystagmus, according to Rucker, is usually a sex-linked character, the gene being carried on the X chromosome In some families hereditary nystagmus is transmitted on an autosome In some this type of nystagmus is associated with red-green color blindness

IRREGULAR OR SPASMODIC MOVEMENTS OF THE EYES Nonrhythmic, irregular movements of the eyes may occur in connection with special ocular paralyses or insufficiencies and errors of refraction. Ménière's disease, when due to lesions of the labyrinth, is sometimes accompanied by forced movements of the eyes. Chronic hydrocephalus and meningitis (basal irritation) may give rise to irregular spasmodic movements of the eyeballs In hysteria the internal rectus and levator palpebrae may be tonically contracted, the eyes being opened, convergently squinted and uprolled.

Asthenopia and Insufficiencies of the Ocular Muscles. If complaint is made that close use of the eyes, such as that involved in writing, reading, or sewing, causes them to feel strained, hot, and uncomfortable, and perhaps gives rise to headache in the forehead, vertex, or occiput, the source of the trouble may be found in a weakness of the ocular muscles, particularly the recti If this weakness exists, the patient cannot keep the visual axes of the eyes in proper relation without an effort, either conscious or unconscious.

If normal strength of the ocular muscles is present, the condition is called *orthophoria*. If some of the muscles are weak, it is termed *heterophoria*

The varieties of heterophoria are. *esophoria*, weakness of the externi, causing a tendency to convergence of the visual axes, *exophoria*, a tendency to divergence of the visual axes from weakness of the interni, *hyperphoria*, a tendency of the visual axis of an eye to deviate upward, *hypophoria*, the tendency of the visual axes to deviate downward

None of these deviations is sufficiently obvious to constitute strabismus. All of these conditions require the advice of an ophthalmologist after he has examined the patient.

The consensus among those trained in ophthalmology and neurology appears to be that the importance of muscular asthenopia in causing various forms of nervous disease has been greatly overrated. According to the more conservative view, muscular asthenopia is not a factor in causing nervous disorders, but in neuropathic individuals it may intensify or render more frequent attacks of migraine, trigeminal neuralgia, occipital and cervical headaches, vertigo, and perhaps choreiform movements of the upper facial muscles The correction of refractive errors and the wearing of glasses may relieve the troublesome symptoms

Nerves of the Orbit. The optic nerve is the nerve of sight. Interference with it produces blindness. This nerve will be discussed separately later in the text.

The oculomotor or third nerve supplies all the muscles of the orbit except the external rectus and superior oblique. If the third nerve is paralyzed, the eye cannot be moved upward, inward, or to any extent downward. There will be ptosis of the upper

The observations which may be made on examining the eyeball relate to pulsations in and around the eye, the protrusion or recession of the eye, its position and its degree of mobility.

Visible pulsation of the eyeball may be found in aortic insufficiency, arteriovenous aneurysm, great cardiac hypertrophy, and vasomotor instability, as in exophthalmic goiter and other conditions in which there is abnormal throbbing of the arteries.

Protrusion. Exophthalmos of a moderate degree is commonly of congenital origin. Protrusion of the eyeball, when bilateral, has as its commonest explanation exophthalmic goiter. The eyes may protrude in asthma or other conditions attended by severe dyspnea. Thrombosis of the superior longitudinal sinus may be attended by unilateral or bilateral protrusion of the eyeball and swelling of the face

Swellings or tumors may displace the eyeballs forward, usually on one side, perhaps on both sides, as in great enlargement of the lacrimal gland and arteriovenous aneurysm, exostosis, cancer of the orbit, or tumors of the upper maxilla. One or both eyes may be pushed downward and forward and come to rest in the upper portion of the orbit by subperiosteal hemorrhages which may be present as one of the lesions of scurvy.

Instruments to measure the protrusion of the eye have been devised, the best known of which is the Hertel exophthalmometer, a satisfactory instrument though somewhat difficult to use. A simpler instrument is the one devised by Luedde, but since the position of the two eyes is not measured at the same time it requires great care to be sure that the instrument is similarly placed on each side in turn The normal reading with the Hertel instrument seems to be about 15 mm , but it is variable.

The protrusion differs with different causes In a general overfilling of the orbit by increase in its contents the eye projects straight forward and can move in every direction This is the condition seen in exophthalmic goiter A tumor within the muscle cone, if not too large, produces the same effect, but a large tumor in the cone tends to move and displaces the eyeball to the side. Tumors in the orbit outside the muscle cone push the eye to one side

Malignant exophthalmos occurs in association with exophthalmic goiter. The exophthalmos may increase despite relief from the toxic symptoms. It has been postulated that this condition is due to a hormone different from the one which causes exophthalmic goiter

Various theories have been propounded to explain the development of exophthalmos by local reasons It has been variously attributed to an increase in the orbital fat, to edema of the normal orbital contents, to congestion of the vascular bed of the orbit, to relaxation and hypertrophic myositis of the extra-ocular muscles, and to contraction of the smooth muscles Exophthalmos may follow paralysis of the ocular sympathetic nerves (see Autonomic Nervous System, Chapter 23).

The malignant type of exophthalmos most commonly occurs in patients aged 40 years or more The sex incidence is almost reversed from that of the incidence of exophthalmic goiter Men are therefore more commonly affected than women. Once a progressive or malignant exophthalmos is established, rarely does a complete regression of the exophthalmos occur The condition may become stationary, or it may progress until disorganization of the eyeball is so great that excision of the globe has to be performed It is now generally accepted that there is an edema of all the orbital tissues outside the globe, and this increase in size of the orbital contents pushes the eyeball forward. It also restricts the free movements of the eyeballs.

Unilateral Exophthalmos. Unilateral exophthalmos occurs as a nonpulsating and as a pulsating form

The most frequent causes of a *nonpulsating unilateral exophthalmos* are retrobulbar tumors of soft tissues, bony orbital tumors or vascular lesions such as varicocele of the ophthalmic veins. Infections of the sinuses, soft tissues and bones

The diplopia is an extremely annoying symptom, as the eye is so constantly employed in writing, reading, and walking, all of these occupations requiring down turning of the eye The head is likely to be carried forward and toward the sound side.

Isolated paralysis of the fourth nerve is very infrequent. When present, it may be indicative of pressure on the nerve trunk as it winds around the outer surface of the crus to reach the anterolateral edge of the pons

The coexistence of symptoms of cerebellar disease with fourth-nerve palsy is indicative of a lesion of the anterior part of the cerebellar hemisphere on the same side. There may be paralysis of the fourth nerve, presumably due to a peripheral neuritis as the result of epidemic influenza, diabetes, alcoholism, lead poisoning and tumor However, such paralysis may be a transient symptom of myasthenia gravis.

Sixth Nerve. A lesion of the nucleus of the sixth nerve may cause conjugate deviation of the paralytic form.

Third, Fourth, and Sixth Nerves. Total ophthalmoplegia may be indicative of disease in the cavernous sinus of the sphenoidal fissure, especially if there is anesthesia of the peripheral distribution of the ophthalmic division of the trigeminal nerve (skin of forehead, upper eyelid and nose) The branches of this division accompany the ocular nerves through the sphenoidal foramen, and they may be involved by lesions in these localities, that is, syphilitic or other periostitis, gumma or other tumor, aneurysm or arteriovenous aneurysm of the internal carotid, or thrombosis of the cavernous sinus

Ophthalmoplegia, external, internal or total, may be a symptom of acute or chronic polioencephalitis superior (upper palsy, nuclear palsy), or encephalitis or botulism

When paralysis of all the ocular muscles is associated with facial paralysis without hemiplegia, it is probably due to a basal lesion, since the facial nerve, like the ocular nerves, is liable to involvement by disease at the base

DIAGNOSIS OF MULTIPLE OCULAR MUSCLE PARALYSES The diagnosis of paralysis of a single ocular muscle may be difficult on occasion When more than one muscle in the same eye is paralytic, a much more difficult task is encountered, and if one or more muscles in each eye are paralyzed, the signs can be confusing, owing to all degrees of paresis of the muscles, and innervational overaction and underaction, spasm, contractures and fibrosis of other muscles not involved It can be safely said that only experienced ophthalmologists are aware of the difficulties that sometimes attend the analysis of ocular muscle paralysis

The ophthalmologist employs the Maddox rods, screen test, test of rotations or ductions, test of versions, test of diplopia fields, past pointing, and head tilting in his diagnostic procedures

Immediately after paralysis is acquired, all the characteristic symptoms and signs, such as diplopia, limitation of motion, primary and secondary deviation, false orientation and the subjective sensations of vertigo and dizziness may be present. As the paralytic condition continues, the original symptoms become modified, diplopia becomes less obtrusive, compensatory head tilting becomes apparent, fixation may change, and unopposed or innervationally overacting muscles may become spastic and undergo contraction with fibrosis The originally nonconcomitant strabismus gradually takes on the characteristics of a concomitant disturbance. The complexity of this transition is multiplied by the simultaneous paralysis of two or more muscles.

POSITIONS OF THE EYEBALL

The positions of the eyeball in its socket are classed as flat, midprominent, or protruding With age the increasing relaxation of the extra-ocular muscles causes the eyes to appear flat or less deeply imbedded than in early life. This change is less marked in women than in men.

of the wound become yellow and necrotic, hypopyon appears, there is chemosis, with intense ciliary and conjunctival congestion, and the lids are swollen and red. The vitreous becomes purulent, as shown by a yellow reflex by oblique illumination. The anterior chamber soon becomes full of pus, and the cornea cloudy and yellow; ring infiltration may occur. There may be exophthalmos and limitation of movement of the globe, due to extension of the inflammation. In the early stages of metastatic panophthalmia rapid failure of vision, a yellow reflex, and hypopyon are found.

If the disease is permitted to take its course, the sclera is ruptured, usually just behind the limbus. The pain subsides, and after prolonged suppuration the eyeball shrinks and vision is lost. Sympathetic ophthalmia is unlikely.

As soon as it is evident that the eye cannot be saved it should be excised.

Sympathetic Ophthalmia. Sympathetic ophthalmia is a rare condition in which serious inflammation attacks the sound eye after injury of the other eye. The disease is thought to arise from an infection.

Sympathetic ophthalmia almost always is caused by a foreign body which remains within the eye without suppuration. Wounds involving the iris, ciliary body or lens capsule without suppuration are likely to set up sympathetic ophthalmia. Perforating ulcers very rarely cause it

Children are particularly susceptible, but the disease occurs at any age. It usually begins 4 to 8 weeks after the injury to the first eye (the exciting eye) has taken place, rarely earlier, but the onset may be delayed for many months or even years.

The manifestations in the second or sympathizing eye are almost always a plastic iridocyclitis, in rare instances a neuroretinitis or choroiditis In other cases the patient first seeks advice for defective vision or inflammation in the uninjured eye (sympathetic irritation)

The symptoms commence with sensitiveness to light and transient indistinctness of objects. Objects become blurred, if the eye is fatigued, but after an interval of rest vision improves When fully developed, all the symptoms of iridocyclitis are present, varying in degree according to the severity of the disease The prognosis as to vision is always doubtful, but if there is much deposition of plastic exudates in the pupillary area, it becomes extremely grave

On examination at this stage there may be lacrimation, slight ciliary injection, tenderness of the eyeball, as shown by the patient shrinking from an attempt at examination, precipitates on the back of the cornea, and vitreous opacities These early symptoms may occur in intermittent attacks, and spread over a considerable period As the disease progresses, the signs of iridocyclitis are present

The treatment of sympathetic ophthalmia is one of the most difficult problems in ophthalmology and often demands the exercise of superior judgment on the part of the ophthalmologist When restoration of sight is doubtful, the eyeball may have to be sacrificed if treatment fails

INJURIES OF THE EYEBALL

Wounds of the conjunctiva, as has been said, are common. They usually heal readily Polypoid masses of granulation tissue sometimes form on the surface during the healing process. A wound of the lens may escape notice at first, especially if the wound is small Later the wound is made evident by the ensuing corneal opacity.

Small wounds of the cornea limited to the center heal well unless they become infected When infections supervene, a permanent dense opacity is left, and the contraction of the organizing scar tissue may cause an irregular astigmatism.

The danger of corneal opacities is greatly increased by a large wound of the eye if it extends into the sclera, or if the lens is also wounded. In the larger wounds of the sclera, prolapse of the iris is almost certain to occur. A physician should never yield to the temptation to replace a prolapsed iris even if this is possible since it may carry infection into the eye. It must be excised.

of the orbit may produce an exophthalmos. Prominence of the eye may occur as a result of an anterior staphyloma or a high myopia.

In the majority of instances *pulsating exophthalmos* is unilateral. The condition usually follows trauma and is the result of a fistula between the internal carotid artery and the cavernous sinus. In some instances a fracture through the base of the skull involving the body of the sphenoid may be demonstrated. Spontaneous instances may occur from rupture of the artery within the sinus, caused by arteriosclerotic plaques, miliary septic aneurysms or congenital weakness of the vessel wall.

The internal carotid artery lies within and is entirely surrounded by a venous channel This arrangement may permit the formation of arteriovenous fistulas with a minimum of trauma The pulsating exophthalmos resulting from an arteriovenous fistula in the cavernous sinus is due to a sudden engorgement of the venous space with arterial blood under high pressure There is a retrograde flow into the ophthalmic veins, with transmitted arterial pulsations and a venous engorgement of the orbital contents and eyelids These changes may occur to a less degree on the opposite side as a result of communications between the two cavernous sinuses.

The diagnosis of unilateral exophthalmos is usually easy, depending on the degree of proptosis Pulsation does not always exist in those cases which occur spontaneously. Following head injuries a bruit, thrill and pulsation usually are present There are headache, disturbance in vision and intracranial noises. The sounds may vary from minor sensations to an almost continuous roaring. The visual field may show a wide range of disturbance. Diplopia may result from an increase in internal or extra-ocular pressures. The presence of chemosis accounts for some of these changes. Blindness may be due to atrophy of the optic nerve, to glaucoma or to cataract

The extrinsic movements of the eye are limited by the proptosis and the alterations in the nerve mechanism of the extra-ocular muscles The retinal findings are not constant and depend on the duration of symptoms. Compression of the common carotid artery will result in a cessation of a bruit, thrill and pulsation when present. Arteriograms may be obtained by the injection of thorium dioxide into the carotid arteries This procedure is useful in diagnosis in obscure cases The radioactivity of this or similar substances should limit its use.

Recession. Enophthalmos, or sinking of the eyeball into the orbit, if bilateral, may be due to absorption of the cushion fat of the orbital cavity such as takes place in prolonged and continued fevers and in cachexias from any cause. It is notably present during severe dehydration and shock It may also be present in consequence of a rapid and exhausting drain on the body fluids, as in cholera, severe diarrhea and large hemorrhages In collapse it may be due to a deficient orbital blood supply.

INFECTIONS OF THE EYEBALL

Panophthalmia. Exogenous and endogenous forms of panophthalmia are recognized. *Exogenous panophthalmia* is generally caused by infected wounds, whether accidental or the result of operations, and by ulcers. The vitreous is usually first affected; organisms grow in it, and purulent cyclitis, retinitis, and choroiditis result. In most instances the deeper parts of the vitreous become infected

Endogenous panophthalmia arises during the course of septicemias or pyemias The small or the larger arteries in the eyeball may become occluded by septic emboli.

The pneumococcus often is responsible for panophthalmia, but the disease may be caused by staphylococci, streptococci, *Escherichia coli*, *Pseudomonas aeruginosa*, *Clostridium perfringens*, and by saprophytic organisms such as *Bacillus subtilis*

In both exogenous and endogenous forms there is fever (temperature 102 to 103 F), headache, drowsiness, and sometimes vomiting There is severe pain in the eye, due at first to iritis, later to increased tension In the exogenous forms the edges

has been done to vision and unless the process of removal will almost inevitably destroy sight Magnetizable foreign bodies are more easily removed than others if the small or the large electromagnet is available.

If the reaction in the eye does not subside in the course of a week or 10 days, as shown by diminution of ciliary injection and cessation of photophobia and lacrimation, the ophthalmologists may advise removal of the eye In the interval the cornea is examined each day by oblique illumination and magnification in search for precipitates. The presence of these is a more definite indication for excision of the eye.

In the presence of considerable prolapse of vitreous as well as of iris and ciliary body, or if the lens is wounded, there is little probability of saving the eye. If it is almost certain that useful vision will be lost, the risks of sympathetic ophthalmia should not be run and the ophthalmologists will advise prompt excision of the eye.

GLAUCOMA

Glaucoma is a disease accompanied by increased intra-ocular tension which results in hardness of the eye, atrophy of the retina, cupping of the optic disk, and blindness. It is supposed to be due to interference with the drainage of the eye and the circulation of the aqueous humor. Glaucoma may be acquired, may occur in families, or may occur sporadically. Glaucoma of acquired origin as a rule is a disease of advanced life. The familial glaucoma occurs usually before the age of 40 years Instances of sporadic glaucoma too may affect middle-aged persons The cause of the disease often is not known Perhaps the most definite thing recognized in its etiology is that there often is a hereditary tendency The disease tends to occur in hyperopic eyes; myopic eyes are far less liable to the disease but they are not entirely exempt There are a number of varieties of glaucoma distinguished by varying symptoms

Acute glaucoma usually is preceded by a number of transitory attacks, during which there is diminution in the acuteness of vision The sight appears to be obscured as by a fog The patient sees a ring or a rainbow of tints around lights.

The cornea, especially in its center, will often show some congestion, that is, it has a clouded appearance There is a feeling of dullness or slight pain in the eyes and head The pupil is dilated and sluggish in action, and the tension of the globe is slightly to moderately increased.

The *acute glaucomatous attack* commences suddenly and violently in one eye during the early hours of the morning. The constitutional disturbance may be so great that the patient is prostrated, with an irregular, intermittent pulse, pallid face and cold extremities.

The pain radiates throughout the entire head and is most intense in the trigeminal nerve Its acute onset, even though associated with nausea, differentiates glaucoma from intracranial conditions The pain is due primarily to pressure on the ciliary nerve and ciliary plexus

Edema of the eyelids is often present. Lacrimation is an important finding, especially in the absence of any external cause, and is primarily due to reflex irritation. In acute inflammatory glaucoma, as contrasted with chronic compensated glaucoma, the increase of intra-ocular pressure is readily determined by palpation

In severe attacks of glaucoma the entire bulbar conjunctiva and sclera present engorged and dilated vessels so uniform that the color is a deep red This congestion is primarily a venous stasis from the increased intra-ocular pressure In some cases minute hemorrhages may be seen

The cornea presents a steamy appearance. Later the epithelium becomes elevated and is edematous The underlying stroma is edematous and is more or less translucent Edema is followed by vesicle formation involving the superficial epithelium

In an attack of inflammatory glaucoma the anterior chamber is shallow. After the iris comes in contact with the posterior surface of the cornea, adhesions rapidly

Occasionally in perforating wounds pyogenic organisms are carried into the eye and cause rapid dissolution of the cornea and panophthalmia. As the result of the panophthalmia the whole of the central part of the cornea is cast off. The infecting organism has generally been found to be *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*).

Wounds of the corneosclera are particularly likely to originate sympathetic ophthalmia.

When perforation of the sclera has occurred, there is reduction in the intra-ocular tension. If the perforation is near the cornea, the anterior chamber is shallow or obliterated. If the wound is large, prolapse of some of the contents of the globe occurs The uvea is easily recognized on account of its pigmentation since the uvea is the iris, ciliary body and choroid, considered together. Very often the gelatinous vitreous can be seen hanging out of the wound. Blood in the anterior chamber and vitreous hemorrhage may be present with or without perforation.

An eye containing a foreign body is likely to be affected by sympathetic ophthalmia When there is present a perforating wound of the eye, it may be difficult to be sure that it does not contain a foreign body. The foreign bodies most likely to penetrate the eye and be retained are slivers of steel, lead, stone and particles of glass Parts or all of copper percussion caps and, less frequently, spicules of wood may penetrate the eye.

A foreign body large enough to be seen by the unaided eye will cause so much damage that the eye may have to be removed Very small particles which penetrate the cornea or sclera and lodge in the deeper parts of the eye are revealed by roentgenographic study. Most intra-ocular foreign bodies are composed of metallic fragments and are thus radiopaque With the exception of glass containing lead in its manufacture, glass does not cast a shadow on the roentgenogram

Depending on the nature of the foreign body, the pathologic condition set up in the eye is profound and varied. For instance, copper causes suppuration of tissues and a leukocytosis even in the absence of pyogenic organisms. This is due to the peculiar chemical irritation of copper Copper in the lens, however, may cause little reaction because the lens is destitute of active blood circulation. Metals other than iron and copper—for instance, lead, zinc, gold and silver—appear to cause little chemical reaction and usually remain quiescent

The foreign body may pass through the cornea or the sclera and originate minimal symptoms If it has passed through the cornea, the wound or scar can be found by examination with oblique illumination and magnification.

A very small foreign body may be retained in the lower part of the anterior chamber and be hidden by the hemispheric shape of the sclera Glass is particularly difficult to locate in the anterior chamber because its refractive index differs so little from that of the surrounding medium

When a foreign body passes into or through the lens, a traumatic cataract is produced which undergoes the usual changes. A hole in the iris is of great diagnostic significance, for it indicates, usually, a perforation by a foreign body. The foreign body may be visible in the lens, either before or after dilatation of the pupil. It is possible for a foreign body to pass through the iris and through the circumlental space without wounding the lens

A foreign body retained in the vitreous or retina when the lens is clear, and there has been little hemorrhage, may be seen ophthalmoscopically. Often the foreign body can be located by the track it leaves through the vitreous. The track is indicated by a gray line The foreign body, generally black, and often with a metallic luster, is surrounded by white exudate and red blood clot. If the particle has been long in the eye, it may have become encapsulated. Particles more than 1 to 2 mm. in size are almost certain to lead to the destruction of the eye

All foreign bodies should be removed by an ophthalmologist unless little damage

perforation may occur relatively early along the perivascular spaces of the ciliary vessels The orbital tissues then become infiltrated. The lymph nodes are not affected; metastasis occurs mainly to the liver but may be present elsewhere. The first manifestations of metastatic sarcoma of the eye may appear months or years after the eye has been removed and may be revealed by enlargement of the liver and by jaundice

Sarcoma of the choroid appears in persons between the ages of 40 and 60 years. It is always primary and involves one eye only.

The symptoms commence with a defect in the field and diminution in sight depending on the exact seat of the tumor. As the tumor enlarges, there is pain in the eye The symptoms are produced more quickly when the tumor is near the macula than when it is peripheral, since vision is affected early. In other cases the tumor has usually attained a considerable size, and the patients may seek treatment for relief of the pain of glaucoma

The cause of the glaucoma is obscure; in some cases it is due to the lens and iris being forced forward, so that the angle of the anterior chamber becomes blocked. In other instances, particularly those of rapid onset, obstruction to the venous outflow from the eye is the probable explanation, the tumor being in some instances so situated as to press on the venous outlet.

On examination sarcoma of the choroid may resemble in its manifestation a primary detachment of the retina or glaucoma. From primary glaucoma, sarcoma of the choroid is distinguished by the fact that sight is involved before the inflammatory symptoms appear, there are no prodromal symptoms such as usually precede glaucoma nor remissions in symptoms, one eye only is involved, the characteristic field of vision in glaucoma is not present, and the unaffected eye presents no symptoms of glaucoma If the detachment of the retina is extensive, differential diagnosis may be difficult; under such circumstances, the eye will be blind

Secondary carcinoma of the choroid occurs sometimes in late stages of scirrhous carcinoma of the breast, more rarely in cancer of other organs.

THE COATS OF THE EYEBALL

The outer strong fibrous coat of the eyeball is the sclera (sclerotic). The vascular middle coat is the choroid The retina or inner coat is the end-organ of sight and is but an extension of the optic nerve (Fig 4-5).

The sclera forms a firm protective covering or case for the delicate retina within. It is continued forward over the front of the eye as the cornea It is essentially a strong membrane which provides protection The common diseases of sclera and cornea are those of weakness If the cornea weakens, it bulges forward and the protrusion is called an *anterior staphyloma* If the posterior part bulges toward the orbit, a *posterior staphyloma* is formed

The cornea has no blood vessels, but from its exposed position it becomes inflamed (keratitis) and ulcerated, and eventually blood vessels may develop into it from its periphery, constituting the vascularization known as pannus The affections of the cornea have been considered earlier.

The weakest portion of this covering for the eyeball is at the junction of the sclera with the cornea On this account blows on the eye cause it to rupture, usually at this point, the tear encircling the edge of the cornea for a variable distance (usually at its upper and inner quadrant) according to the force and direction of the injury On healing, a staphyloma may form at this point

[illegible]

familial type of disease in which successive generations contain members who have fragile bones, among other members who are healthy; the latter have white scleras Those who have fragile bones have scleras which are definitely blue in color.

form within 24 hours. After 36 to 48 hours these adhesions become so dense that it is often impossible to break them except by operation. The dilated, often irregular and rigid pupil is one of the most characteristic objective symptoms in acute congestive glaucoma.

In a severe attack of acute inflammatory glaucoma the vision is severely reduced, often to light perception. No part of the fundus can be seen with the ophthalmoscope. If the condition progresses, the increased tension of the eyeball causes an extravasation into the optic nerve disk which results in blindness

Often the ophthalmologist discovers a simple glaucoma, the diagnosis of which is made by observing the acuity of vision, charting the visual field, making repeated estimations of the tension, and interpreting the findings presented when the ophthalmoscope and the slit lamp have been employed in the examination. Simple glaucoma is often difficult to discover because tension of the eyeball is not always present at the time of the examination, the tonometer may reveal a rise in tension only after repeated tests on different days. Progression of the disease destroys vision.

The patient complains of dimness of vision with the appearance of concentric rings of color surrounding the source of bright light; for instance, a street light.

TUMORS OF THE EYEBALL

The irides may contain dark brown spots (melanomas), due to congenital aggregations of retinal pigment epithelium As a rule, these are benign but occasionally they take on malignant proliferation Any increase of size of such spots in middle-aged persons causes anxiety to the ophthalmologist

True intra-ocular tumors are rare When they are present, they are of two varieties; namely, retinoblastomas or gliomas of the retina, and sarcomas of the choroid The sarcomas of the choroid are frequently referred to as malignant melanomas.

Retinoblastoma. The retinoblastoma, commonly known as glioma of the retina, probably always congenital, occurs in children less than 5 years old, usually in one eye, but often in both, occasionally in successive children of the same family. The attention of the parents is attracted by the yellow reflex, easily seen through the pupil, which is usually dilated

The ophthalmoscope shows small whitish or yellowish plaques (calcium deposits) with metallic luster, either covered by detached retina or growing into the vitreous, the surface often presenting newly formed blood vessels and sometimes hemorrhages

In the glaucomatous stage there are pain, increase of tension and other symptoms of glaucoma. The tumor increases in size and extends into the vitreous. Very soon the growth can no longer be seen on account of turbidity of the media.

As the tumor increases in size, there are enlargement of the globe and exophthalmos, and then perforation takes place The growth passes backward along the optic nerve to the brain, and forward through the cornea and sclera, increasing in size rapidly, involving all tissues with which it comes in contact and forming a large vascular and ulcerating mass. Metastasis occurs to the neighboring lymph nodes and to the cranial bones, and becomes widespread, causing death

Sarcoma. Sarcoma of the eye arises in the iris, choroid and retina. Sarcoma of the *iris* grows rapidly, extends to the corneosclera, perforates the globe and gives rise to metastasis. Sarcoma of the *choroid* arises from malignant proliferation of the stroma cells of the outer layers. It forms at first a mass, raising the retina over it. By the process of growth, increased tension is produced, and rupture occurs in the subretinal space. The *retina* remains in contact with the tumor at the summit of the head, but is detached from the choroid at the sides. As the tumor progresses, the retina is more and more detached, until no part remains in situ The lens then becomes opaque. The tumor may fill the globe before perforating the sclera, or

Diseases of the Iris and Ciliary Body. The iris, the ciliary body and the choroid form the second coat of the eyeball. The iris is in front, the ciliary body is contained in the folds of the choroid, which forms with the lens the partition between the anterior and posterior chambers of the eye. *All these structures contain blood vessels and thus* are the source of the nourishment for the eye. These structures together comprise the uvea or uveal tract Disease affecting one of these structures is likely to involve all of them and may be termed uveitis.

The *iris* is a circular membrane with a circular opening, the pupil, which serves to [illegible] the lens to the interior of the eye. The iris [illegible] the pupil is contracted and it hangs free of [illegible]nt of disease conditions of the uvea, advantage is taken of these responses of the iris

The color of the iris depends on pigmented cells of its stroma and on the cells of the retinal pigmented layers The muscles of the iris are the sphincter pupillae (third cranial nerve) and the dilator pupillae (sympathetic innervation).

The *ciliary body* is contained within that portion of the tunica vasculosa stretching from the anterior part of the iris to join the choroid It is composed of the ciliary muscle and the ciliary processes, blood vessels and nerves.

The blood supply is derived from the greater circle of the iris and the anterior ciliary arteries. Some of the veins pass posteriorly to join those of the choroid, while others from the ciliary muscles pierce the sclera and course beneath the conjunctiva.

The ciliary processes are meridianally arranged vascular folds forming a circle These vascular folds supply nutrient fluids to the interior of the eye, especially the cornea and lens. The ciliary muscle is the muscle of accommodation. When it contracts, it draws the ciliary processes and choroid forward and inward, thus allowing the suspensory ligament to relax and the lens to become more convex. The ciliary body contains within its substance a nerve plexus with ganglion cells.

The congenital malformations of the iris include pupillary membranous changes. Normally the membranous covering of the pupil is absorbed, but part may persist. Of the congenital malformations of the iris the common one is *coloboma*, a notching in the inferior half of the iris, and often associated with coloboma of the choroid

Occasionally the two irides will be of different colors, or a part of an iris may have a different color from the rest This condition is known as *heterochromia*. It may be due to iritis but more frequently it is congenital

Loss of Power of Accommodation. In paralysis of the ciliary muscle distant objects can be clearly seen but near objects are indistinct This condition must not be confused with (1) reflex iridoplegia (loss of the pupillary light reflex) or (2) accommodative iridoplegia (loss of the pupillary contraction for near vision). Reflex iridoplegia and accommodative iridoplegia both depend on the integrity of the same portion of the oculomotor nucleus Cycloplegia is one of the symptoms of complete third nerve paralysis, is a common symptom in diphtheritic paralysis, and may be present in multiple sclerosis

Iritis, Iridocyclitis and Uveitis. In consequence of its vascularity the iris is a frequent site of inflammation When inflamed, it may adhere to the lens behind, forming a posterior synechia An anterior synechia is an adhesion in which, on account of a perforation of the cornea, the iris washes forward and becomes attached to the cornea in front

Inflammation of the iris is so frequently associated with inflammation of the ciliary body that in most cases these two conditions can be distinguished *only by an* experienced ophthalmologist *Consequently, here this condition will be described* as *iridocyclitis*, which means an inflammation that involves the iris, the ciliary body and often the choroid.

The causes of iritis and often iridocyclitis, if the involvement is more pronounced and accompanied by a more intense pericorneal injection, tenderness *in the ciliary* region, swelling of the upper lids, turbidity of the aqueous, and increased tension.

Diseases of the Sclera. Diseases of the sclera are not common. The most frequent disease of the sclera is inflammation, which may be either superficial or deep. The superficial inflammations of the sclera are generally of the lymphatic part. Scleritis, however, an inflammation of the sclera involving the entire thickness, is a serious condition characterized by severe pain, frequently extending to the neighboring parts of the eye and to the forehead. In this condition the tension of the eyeball often becomes increased and a secondary glaucoma ensues. On examination there are discernible well-marked violet patches or dark red patches adjacent to the cornea. If uveitis, as is often the case, accompanies the scleritis, vision is often interfered with and may sometimes be lost entirely. Thinning and bulging of the sclera are known as staphyloma of the sclera

Diseases of the Choroid. The choroid or vascular coat of the eyeball extends forward and is folded at the separation of the anterior chamber of the eye from the posterior chamber

Coloboma. Coloboma of the choroid is a congenital defect of the choroid and retina which is manifested by a large white patch bordered with pigment, usually situated below the disk. The white patch is the exposed sclera. Retinal vessels pass across this area. There is a scotoma (or scotomas if the condition is bilateral) corresponding to the defect or defects.

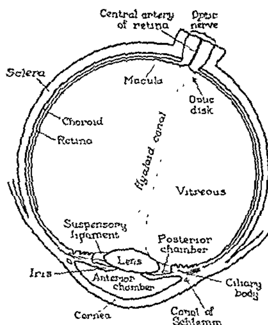

Fig. 4-5 Coats of the eyeball and associated structures

Inflammation. Inflammation of the choroid, or choroiditis, may be suppurative or exudative. Suppurative choroiditis occurs when the choroid with other ocular structures is involved in a purulent inflammation, usually extending from the orbit

The common form of choroiditis described by the ophthalmologist is the exudative form and properly termed *chorioretinitis.* It may be caused by syphilis or tuberculosis, but usually no cause can be assigned. This condition does not present any external symptoms or signs. The patient complains of disturbances of sight, diminution in vision due to opacities in the vitreous, distortion of objects, and a reduction or loss of vision in that part of the field which corresponds to the area of exudation. Very often the patient complains of seeing a black spot, which is the manifestation of a positive scotoma. There are often flashes of light, sparks or bright circles before the eyes

If an area of the retina which is concerned with peripheral vision is involved, the defect of vision may not be noticed, but if the macula is involved, the complaint will be a marked reduction or loss of central vision

On ophthalmoscopic examination the vitreous often is hazy, and patches of exudation varying in size, shape and position are reported by the ophthalmologist. The areas of exudation are colorless with ill-defined margins. There is elevation of the retinal vessels which pass over these areas. In mild instances the exudation may become absorbed. More commonly, however, the exudate becomes organized and, owing to thinning of the areas of exudation, the whitish sclera shows through. Through these thinned atrophic areas choroid vessels surrounded by black pigment, especially at the margins, are reported

responding half of the optic nerve. When the nerve reaches the optic chiasm, it splits into two parts, one (internal fibers) going to the opposite side of the brain, and the other (external fibers) to the ganglia on the same side of the brain. Posterior to the chiasm the nerve fibers form the optic tracts The optic tracts, after leaving the chiasm, wind around the crura cerebri to the external geniculate bodies; thence they pass to the thalami and anterior corpora quadrigemina and are continued backward into the cuneus lobule of the occipital lobe of the brain.

The retina is an extension of the optic nerve dispersed over the whole inner part of the lining coat of the eyeball Where the optic nerve begins, this dispersion is termed the disk. In the visual fields there is a blind spot corresponding to the disk. Away from the disk are the macula lutea and fovea centralis or region of most distinct vision.

Hereditary Degeneration. In pigmentary degeneration of the retina morbid heredity is definite. The characteristic may be dominant, recessive or sex-linked recessive. The disease occurs from soon after birth, to and through middle life

The ophthalmologist describes first a narrowing of the field of vision and twilight and night blindness. The optic nerve head is usually pale There are deposits of dark pigment, irregular in size and shape, connected by fine pigmented lines. The *pigmentation is midway between the extreme periphery of the retina and the region* of the macula, and is bilaterally symmetric. The macular region is the last part of the retina to be involved. The disturbances of vision correspond to the retinal lesions. The retinal vessels are reduced in size. The retina is atrophic and choroidal vessels are exposed. The progress of the disease is slow, and there are no remissions

Congenital deaf-mutism, polydactylism, defect of genital development, mental defect, convulsions, epilepsy and obesity like that seen in Frolich's syndrome are often associated with pigmentary degeneration (see Chapter 15).

The diagnosis is usually made with ease by an experienced ophthalmologist.

Acquired Degeneration. The retina may undergo a chronic progressive degeneration consisting of atrophy of the retina with characteristic deposits of pigment. Along with or as a part of general retinitis there may be a *macular degeneration*. The condition is bilateral, the maculae are the seat of pigmentary changes, and central vision is reduced This commonly occurs in elderly people.

Obstruction of the central vessels of the retinas causes immediate blindness If the artery is obstructed, the retina is pale with a cherry red spot at the fovea. If the vein is obstructed, there are congestion and enlarged tortuous veins present everywhere in the fundus.

Retinitis. Inflammation of the retina is rarely limited to the retina alone, but usually is associated with disease of the choroid and is thus termed chorioretinitis. Inflammation of the retina may be associated with inflammation of an optic nerve, and if so, is known as neuroretinitis

As retinal disease is usually secondary to some extraocular cause, it is in the majority of cases a bilateral affection The varieties and diagnostic significance will be indicated in various parts of this text A partial listing is as follows:

Neuroretinitis of hypertension occurs in cases of arterial hypertension (see Hypertension, Chapter 10). The papillitis may be so marked that it is difficult to determine whether it is of vascular or of intracranial origin. In neuroretinitis the retinal vessels are altered and seem interrupted where they are covered by the swelling. The arteries are thin; the veins are tortuous and distended. There are flame-shaped hemorrhages and the so-called cotton-wool exudates. *Neuroretinitis of glomerulonephritis* is distinguishable from that occurring in hypertension (see Diseases of the Kidneys, Chapter 11). In *congenital syphilis* retinitis pigmentosa may occur. In acquired syphilis both retina and choroid are likely to be affected and the chorioretinitis is regarded as a secondary symptom. About 1 of every 4 who have leukemia has retinitis (*leukemia neuroretinitis*). *Diabetic retinitis* seems to be characteristic (see Diabetes Mellitus, Chapter 14).

The symptoms of affections of the retinas are marked disturbances of vision or

are the same. The distinction in the terms is based rather more on degree of involvement than on the anatomic structures involved.

Both iritis and iridocyclitis have often been attributed to *chronic focal infection.* However, there are but a few patients who have the disease in whom focal infections can be demonstrated Abnormal intestinal flora and intestinal toxins cannot be demonstrated. Iridocyclitis may be a part of: (1) Syphilitic iritis or iridocyclitis which occurs during the secondary stage of syphilis; (2) Gonorrheal iritis or iridocyclitis which occurs in a few of those who have gonorrheal urethritis; (3) Tuberculous iritis or iridocyclitis which occasionally occurs; (4) Iritis or iridocyclitis which may be mentioned as a complication of diabetes, gout and rheumatism.

Despite the fact that all are agreed that usually an iritis or an iridocyclitis is of systemic origin, general examinations often do not disclose a definite cause.

The chronic or relapsing form of iridocyclitis, which often affects younger persons, frequently is termed uveitis.

The symptoms of iridocyclitis consist of pain, photophobia, lacrimation and interference with vision. The pain is often severe and may be referred to the region of the eyeball, or it may extend to the forehead or temple; it is worse at night than by day. Often there is tenderness of the eyeball On examination the iris appears swol-

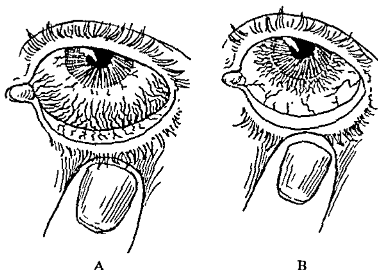

Fig 4-6. Distribution of dilated blood vessels in conjunctivitis and in iridocyclitis A, conjunctivitis B, iridocyclitis

len and dull, it has lost its color and is now greenish blue or gray and may be of a smoky appearance The pupil is contracted, irregular and sluggish in action One of the most characteristic of the external appearances of this condition is a marked circumcorneal injection and more or less conjunctival injection. It is important that iridocyclitis be differentiated from an acute catarrhal conjunctivitis, because in iridocyclitis the instillation of atropine is most important in treatment (Fig 4-6). Likewise the condition should be differentiated from glaucoma because the instillation of atropine in a glaucomatous eye is disastrous It should be remembered that generally in iritis the pupil is small, gray and sluggish and irregular in outline after the use of atropine In glaucoma the pupil is dilated, oval and immovable The cor- [illegible] cornea in glaucoma is insensitive In acute iritis the [illegible] whereas in glaucoma the conjunctiva is congested [illegible] ill tension is usually normal; in glaucoma, it is increased.

Diseases of the Retina. On the interior of the eye the expansion of the optic nerve forms the retina. The retina is divided into two lateral halves, each supplied by a cor-

Pathologic Conditions. There are three varieties of paralysis of the iris, or iridoplegia, with pupils small or of medium size, as follows: (1) loss of response to *light*—reflex iridoplegia; (2) loss of response to *accommodation*—accommodative iridoplegia; (3) loss of response to *irritation of the skin of the neck*—absent skin reflex

Common Abnormalities of Iris and Pupil. The common abnormalities of the iris and pupil, together with their possible diagnostic indications, may be stated as follows:

Iris and Pupillary Outline. Inflammation of the iris is often of idiopathic origin If iritis is present, the iris, if normally blue or gray, becomes darker, the pupil responds sluggishly to the light and, if the disease is unilateral, is smaller than the other pupil because of the iritic congestion and consequent swelling. There is a narrow zone of pinkish hyperemia around the edge of the cornea. If the iris is brown or black, little change of color occurs. While one iris may normally differ in color from the other, if one is green and the other blue the existence of iritis should be strongly suspected In many cases iritis is unilateral and is prone to relapse. Syphilitic iritis occurs only during the secondary stage of the disease, is commonly bilateral, and rarely relapses.

An irregular outline of the pupil is due to iritis and subsequent adhesions between the posterior surface of the iris and the anterior surface of the lens, posterior synechia.

Anisocoria. Inequality of the pupils may be present in healthy persons and in those whose eyes refract unequally.

Adie's Syndrome. Adie's syndrome is an anomaly in which there is one myotonic pupil, often associated with absent tendon reflexes. The condition is generally unilateral and the defective pupil is larger than its fellow The cause is unknown except in instances where it is associated with the Pancoast syndrome

Hippus. A rapid contraction and dilatation of the pupil on sudden exposure to light is normal in some healthy persons It is also seen in the early stage of acute meningitis, in disseminated sclerosis and in hysteria In Cheyne-Stokes respiration the pupils may be dilated during the period of rapid breathing and contracted in the apneic interval

Argyll Robertson Pupil. If the pupil does not respond to light and shade, but does respond to accommodation, it is of the type called the Argyll Robertson pupil. The condition most frequently is present as a symptom of locomotor ataxia and perhaps is due to changes in the third nerve nucleus which presides over the light reflex, the portion which regulates the accommodative contraction not being involved The loss of the light reflex may also be due to degeneration of the ciliary ganglion The pupil in this condition is usually contracted because the lesions in the cervical segment of the spinal cord interfere with the dilating mechanism Late in the disease the accommodation reflex also may be lost A similar pupillary condition is seen as a symptom of intracranial syphilis and progressive paresis of the insane

Accommodative Iridoplegia With Preserved Light Reflex. This condition is the opposite of the Argyll Robertson pupil It is of infrequent occurrence and may denote a lesion affecting a portion of the oculomotor nucleus in which lie the cells causing accommodative reaction It may also, but not always, exist with the cycloplegia which occurs after diphtheria

Unilateral Dilatation. One pupil may be dilated as the result of disease of the optic nerve, as in optic atrophy, or there may be lessened transparency of the media, as in cataract and glaucoma If the pupil of the diseased eye does not react directly to light, but does react when the light is thrown into the sound eye (consensual or indirect reaction), it shows that the disease is in the optic nerve or tract and that the oculomotor nerve of the diseased side, its nucleus, and nuclear connections with

complete blindness. In the beginning, the field of vision is usually contracted peripherally for colors and there may be reversal of the color field. The blind spot is enlarged and hemianopsia or scotomas may be present.

Examination for disorders of the retinas is performed by means of the ophthalmoscope and direct retinoscopy Retinitis is almost always bilateral and does not present external signs or symptoms. Examination reveals an indistinctness of retinal details, congestion of the disk with blurring of its edges. A retinitis is characterized by circumscribed exudations appearing as soft, white spots or patches of variable size which may be discrete or confluent. The spots occur principally along the retinal vessels and in the macular region. Often there are tortuosity and distention of the retinal veins, which appear to be darker than they are when normal The vessels may be obscured in part by swelling and exudation Hemorrhages are present and are often described as rounded, soft, or flame-shaped. In retinitis accompanied by choroiditis, opacities in the vitreous may be seen

Retinal Hemorrhage. The vascular changes accompanying arterial hypertension are the commonest cause of retinal hemorrhages as described in the section on hypertension. Chronic nephritis may be the causative condition and so also may the hemorrhagic blood states, as in scurvy, hemophilia, purpura and the grave anemias Retinal extravasations may also be significant of malarial fever, septicemia, pyemia and leukemia, although in the last a retinitis is commoner than retinal hemorrhage

Detachment of Retina. The retina may become detached. When it is detached, there is a loss of vision in the visual field of this part of the retina A small loss of vision from a detachment of the retina may not be noticed by the patient. However, if there is an extensive detachment of the retina, the patient observes a visual disturbance which may be described as a cloud or curtain hung before the eye Early *symptoms are metamorphopsia*, and flashes of light, or photopsia. Detachments of the retina are easily visualized by means of the ophthalmoscope They are commoner in myopic eyes than in other types of eye

THE PUPIL

The pupil is the aperture in the iris which controls the amount of light reaching the lens and consequently the interior of the eye The points to be observed about the pupil are its state of dilatation or contraction, inequality (anisocoria), response to light, response to accommodation, and the skin reflex

The responsiveness of the pupil to light is determined for each eye separately by the use of an artificial light or by asking the patient to look at the light from a window With the patient still keeping the eyes in the same direction, the hands of the physician are placed over and close to, but not touching, the eyes One hand is then suddenly removed, and the behavior of the pupil is noted Normally the pupil contracts on exposure to light—the *direct reflex* In normal eyes the pupil of the covered eye will also contract—the *indirect reflex* Particular care in this examination is desirable. Artificial light in a dark room should be employed In the modern lighted room the light reflex cannot be determined with the lights on Turn the lights off before attempting to test for the light reflex with an artificial light. While the patient, with one eye covered, looks toward the darkest part of the room, the light is brought suddenly before the uncovered eye, at a distance of 3 or 4 feet (about 91 or 122 cm.) so that the pupillary accommodation reflex may be eliminated.

Response to Accommodation. Since the pupil grows smaller when the eyes converge and the ciliary muscle contracts in the act of accommodation for near objects, this function should also be examined. Let the examiner place his finger tip 12 or 15 inches (30 or 38 cm) from the eye, nearly in line with some distant object, and direct the patient to look first at the finger and then at the distant object until it is decided whether or not the pupil contracts when the patient is looking at the finger.

Pathologic Conditions. There are three varieties of paralysis of the iris, or iridoplegia, with pupils small or of medium size, as follows: (1) loss of response to *light*—reflex iridoplegia; (2) loss of response to *accommodation*—accommodative iridoplegia; (3) loss of response to *irritation of the skin of the neck*—absent skin reflex.

Common Abnormalities of Iris and Pupil. The common abnormalities of the iris and pupil, together with their possible diagnostic indications, may be stated as follows:

Iris and Pupillary Outline. Inflammation of the iris is often of idiopathic origin. If iritis is present, the iris, if normally blue or gray, becomes darker, the pupil responds sluggishly to the light and, if the disease is unilateral, is smaller than the other pupil because of the iritic congestion and consequent swelling. There is a narrow zone of pinkish hyperemia around the edge of the cornea. If the iris is brown or black, little change of color occurs. While one iris may normally differ in color from the other, if one is green and the other blue the existence of iritis should be strongly suspected. In many cases iritis is unilateral and is prone to relapse. Syphilitic iritis *occurs only during the secondary stage of the disease, is commonly bilateral, and* rarely relapses.

An irregular outline of the pupil is due to iritis and subsequent adhesions between the posterior surface of the iris and the anterior surface of the lens, posterior synechia

Anisocoria. Inequality of the pupils may be present in healthy persons and in those whose eyes refract unequally

Adie's Syndrome. Adie's syndrome is an anomaly in which there is one myotonic pupil, often associated with absent tendon reflexes. The condition is generally unilateral and the defective pupil is larger than its fellow The cause is unknown except in instances where it is associated with the Pancoast syndrome.

Hippus. A rapid contraction and dilatation of the pupil on sudden exposure to light is normal in some healthy persons. It is also seen in the early stage of acute meningitis, in disseminated sclerosis and in hysteria In Cheyne-Stokes respiration the pupils may be dilated during the period of rapid breathing and contracted in the apneic interval

Argyll Robertson Pupil. If the pupil does not respond to light and shade, but does respond to accommodation, it is of the type called the Argyll Robertson pupil The condition most frequently is present as a symptom of locomotor ataxia and perhaps is due to changes in the third nerve nucleus which presides over the light reflex, the portion which regulates the accommodative contraction not being involved The loss of the light reflex may also be due to degeneration of the ciliary ganglion The pupil in this condition is usually contracted because the lesions in the cervical segment of the spinal cord interfere with the dilating mechanism. Late in the disease the accommodation reflex also may be lost A similar pupillary condition is seen as a symptom of intracranial syphilis and progressive paresis of the insane

Accommodative Iridoplegia With Preserved Light Reflex. This condition is the opposite of the Argyll Robertson pupil It is of infrequent occurrence and may denote a lesion affecting a portion of the oculomotor nucleus in which lie the cells causing accommodative reaction It may also, but not always, exist with the cycloplegia which occurs after diphtheria.

Unilateral Dilatation. One pupil may be dilated as the result of disease of the optic nerve, as in optic atrophy, or there may be lessened transparency of the media, as in cataract and glaucoma If the pupil of the diseased eye does not react directly to light, but does react when the light is thrown into the sound eye (consensual or indirect reaction), it shows that the disease is in the optic nerve or tract and that the oculomotor nerve of the diseased side, its nucleus, and nuclear connections with

the corpora quadrigemina, and through the latter with the opposite optic tract, are not involved. Unilateral dilatation may be due to irritation of the cervical sympathetic by a tumor of the neck, by aneurysm of the aorta, and when limited to the right eye, by an aneurysm of the innominate artery. One pupil is dilated in unilateral paralysis of a third nerve.

Bilateral Dilatation. Double atrophy, amaurosis or blindness from any cause will obviously give rise to dilatation and failure of the light reflex. Mydriasis may result from syncope, shock, nausea and aortic regurgitation. The pupils may be dilated in neurasthenia, hysteria and strong emotion; in severe dyspnea and asphyxia; in cerebral hemorrhage, thrombosis, tumor and abscess; in the later stages of meningitis and diphtheritic paralysis, from lesions of the oculomotor nerve or nucleus; in coma following an epileptic convulsion, and after administration of drugs. Some of the drugs which have a mydriatic action, local or constitutional, are alcohol, atropine, chloral, chloroform, cocaine, hyoscyamus, nitrous oxide, strychnine and tobacco

When both pupils are dilated, the eye has a peculiarly brilliant expression, which may be particularly noticeable in mania, in fevers attended with active delirium, in exophthalmic goiter, and in poisoning with belladonna.

Contracted Pupils. Contraction of the pupils (miosis) may be due to irritation of the oculomotor system, to paralysis of the dilators or to the administration of drugs

The pressure of a mediastinal tumor, if sufficiently great to paralyze the sympathetic (dilator) fibers in the upper part of the thorax, may explain unilateral miosis. Unilateral cerebral lesions, so placed and of such a character as to irritate the oculomotor center, may cause unsymmetric miosis

A certain degree of miosis and sluggish contraction of the pupil is normal in old age. The pupils are contracted during sleep in a healthy person

Congestion of the iris, such as occurs in the injected eyes in rickettsial fevers, causes miosis; so also with mitral insufficiency and other conditions producing venous congestion The pupils are contracted in retinitis and when photophobia exists

Bilateral disease of the cervical segments of the spinal cord and spinal column, by paralyzing the sympathetic dilator fibers, may allow miosis Symmetric miosis may thus be significant of locomotor ataxia in particular, disseminated sclerosis, general paresis, spinal meningitis, tumor or hemorrhage of the cord, bulbar paralysis, hemorrhage into the pons, and tuberculous disease of the cervical vertebrae. Irritating lesions of the brain—notably cerebral meningitis, cerebral or dural hemorrhage and tumor or abscess of the brain—by stimulating the third nerve center, will cause miosis. Miosis is present in the early stage of sunstroke and may also be present in the uremic state

Certain drugs have a characteristic action in contracting the pupil, particularly opium and its alkaloids. Others are eserine and pilocarpine

Absent Skin Reflex. If the pupil does not dilate when the skin of the neck is pinched or pricked, it may be due to the atrophy of the iris in a glaucomatous eye or to posterior synechia following iritis It is not infrequent in general paresis.

DISEASES OF THE LENS

The alteration of the refractive power of the lens is accomplished by changes in diameter and in shape of its anterior surface according to the distance between the [illegible]

lens invariably result in loss of transparency in the parts affected This condition of partial or complete loss of transparency is called cataract.

Cataract. The earliest stage in the development of cataract is an accumulation of fluid either as droplets beneath the capsule or in spindle-shaped spaces between the lens fibers. Clinically this stage can be recognized by inequalities in the refractive indices of the fibers and fluid which give rise to light and dark streaks when light is thrown into the eye by the mirror.

The essential and common factor in the production of cataract is the coagulation of the proteins of the lens which accompanies advancing years However, many different factors, such as radiant heat, luminous and ultraviolet rays, and radium, may cause cataracts. Ultraviolet rays alter the permeability of the lens capsule. Dinitrophenol, used for reducing body weight, may produce posterior cortical cataract The occurrence of cataract in tetany due to parathyroid deficiency suggests a definite association with the role of calcium metabolism Cataract also occurs in association with myotonia atrophica and ergotism

Cataracts are classified according to the situation and the extent of the opacity or opacities in the lens and according to the age of the patient.

Cataracts of Congenital Origin. The commonest forms of congenital cataracts are lamellar and anterior capsular; less common are the central or total.

Lamellar cataract occurs early in infancy. The opacity in lamellar cataract is situated in the layers surrounding the center of the lens, which itself usually contains punctate opacities; the superficial cortex is clear. Lamellar cataract is due to a period of malnutrition at some stage of late intra-uterine or early infantile life. Epithelial structures are most affected, and characteristically epithelium persists where ordinarily it is cast off. Epithelium persists in the lens and in the enamel of the teeth. Lamellar cataract is almost invariably accompanied by defective enamel in certain of the permanent teeth. The hypoplasia differs essentially from the condition of the teeth in congenital syphilis It is often due to maternal rubella.

Cataracts may result from premature birth

Anterior and posterior cataracts are of congenital or acquired origin. Anterior cataracts are designated anterior capsular and anterior cortical The posterior cataracts are posterior opacities called posterior polar and posterior cortical cataracts.

The child is brought for examination on account of defective vision Objects are held very close to the eyes

Senile Cataract. A senile cataract rarely occurs in persons less than 50 years of age Cataract occurs equally in men and women. It is usually bilateral, but develops earlier in one eye than the other. Cases of hereditary predisposition have been recorded, and in some of these the cataract develops at an earlier age in successive generations.

The appearance of black spots in front of the eyes is usually the first symptom. The spots differ from the ordinary muscae volitantes occasionally complained of in normal eyes, and much exaggerated in cyclitis, in that they are stationary, retaining their relative position in the field of vision in different positions of the eye. There may be doubling or tripling or even more duplication of the objects seen. This is often worse on looking at bright lights Eventually the central area becomes affected and vision steadily diminishes until only perception of light remains.

The pupil in old people is seldom so black as in the young, and is sometimes distinctly gray. If the grayness is uniform, cataract is not diagnosed unless definite opacity is shown on examination with the ophthalmoscope. This grayness without opacity is caused by increase in the refractive index of the cortex of the lens in old people, and is due to increase of reflection and scattering of light

The nucleus in the common senile cataract undergoes little change and does not become opaque, but eventually the whole of the cortex is cataractous. The cataract is then said to be ripe or *mature* At this stage it will be found that the anterior chamber has regained its normal depth. The watery fluid has been absorbed from the lens, which has again returned to its normal volume. *This is an important guide* to the most favorable time for operation

In *incipient* senile cataract radial spokes or sectors of opacity are seen, with clear areas between them. They are difficult to see in daylight or by oblique illumination, and cataract cannot be diagnosed without confirmation with the ophthalmoscope With the pupil undilated, only the ends of the spokes are seen, but when the pupil is dilated, the linear opacities are often found to be the apices of sectors, with their bases toward the periphery. They generally begin in the lower part of the lens, especially the lower nasal quadrant.

Secondary Cataract. A form of secondary cataract is the opacity which persists or follows after the extraction of the lens.

Cataract in diabetic persons is by no means always diabetic in the proper sense of the term Senile cataract of the usual type, following the usual course, often occurs in elderly diabetic patients. Cataract in young diabetic patients is a secondary or complicated cataract and termed *diabetic cataract.*

Owing to exposure to roentgen rays or radium, cataracts may form *Irradiation cataract* resembles the early posterior cortical stage of *glassworkers' cataract* One course of deep roentgen rays may suffice There is a considerable latent period, which may be at least two years Only the gamma rays of radium seem to be nocuous.

THE VITREOUS BODY

Opacities. Black specks, floating before the eyes, may be seen by normal persons These specks (muscae volitantes) are opacities of various kinds which cast shadows on the retina, thus appearing as dark spots in the field of vision The corpuscles circulating in the retinal blood vessels at times may be seen as golden-colored specks Other muscae may be due to small specks in the vitreous Some types of muscae cannot be seen with aid of the ophthalmoscope.

Under abnormal conditions muscae may be of sufficient numbers to interfere with vision and to become visible by the ophthalmoscope They then indicate some disease of the uveal tract, particularly of the ciliary body; they are found in cyclitis and choroiditis In the more severe instances muscae may resemble flakes and threads. Such large opacities are often present after hemorrhage into the vitreous.

Fluid Vitreous and Specks Before the Eyes. Fluid vitreous is common in cases in which opacities are present, and is associated with the same causes The degeneration of the vitreous which leads to fluidity often causes the deposition of crystals of cholesterol, which sink to the bottom of the vitreous chamber, but are stirred up by movements of the eye. They then appear as a shower of specks of a bright yellow color (synchysis scintillans).

Blood. Hemorrhage into the vitreous may result from arteriosclerosis or inflammation of the retina, from contusions or wounds of the eye or may appear without apparent cause Hemorrhages, filling the vitreous with blood, are suspected when no reflex can be obtained on throwing in light with the mirror It may then be possible to see a red mass behind the lens by oblique illumination

Severe vitreous hemorrhage may occur in apparently healthy young adults *It* has a great tendency to attack both eyes in succession and to recur, so that though absorption may be complete in the early attacks, permanent defect or complete loss of sight, retinitis proliferans, or dense vitreous opacities may ultimately follow from damage to the retina It is characteristic of vitreous hemorrhage that absorption usually takes place without organization, owing to the absence of fibroblasts in the vitreous. When organization occurs, as in so-called retinitis proliferans, it is most marked near the disk, from which membranes and strands stretch forward. Even [illegible] the absence of some general disease.

[illegible] is present in the vitreous in *cases of plastic* [illegible] membranes stretching across behind the lens. In [illegible] in syphilitic and possibly tuberculous subjects, minute bunches of newly formed blood vessels project from the disk or retina.

Parasites. Cysticercus, when present, may be seen ophthalmoscopically as a pearly translucent mass with peristaltic movements

THE OPTIC NERVE

As the optic nerve enters the eye, it is contracted and forms the disk or papilla It is readily seen with the ophthalmoscope as a round spot somewhat lighter in color than the surrounding eyeground. Coming from a depression or cup in the disk, called the porus opticus, are the retinal arteries and veins. A certain amount of cupping is normal, but if wide and deep, with overhanging edges over which the vessels can be seen to dip, it is indicative of glaucoma.

Sometimes, as in brain tumor and in malignant hypertension, the papilla, disk or optic nerve head is swollen. When this condition occurs, it is called choked disk or papilledema.

Inflammations of the optic nerve, known as optic neuritis, consist of two groups of affections, one arising within the eyeball (papillitis) and the other arising behind the eyeball (retrobulbar neuritis).

Papilledema or Choked Disk. Papilledema or choked disk is a noninflammatory swelling of the optic nerve head which often results from increased intracranial pressure, from malignant hypertension, or from obstruction of the orbital veins. The condition is usually bilateral, though there may be different degrees of swelling in the two eyes. In rare instances only one eye is affected

On ophthalmoscopic examination of the fundus in instances of intracranial hypertension there are swelling and protrusion of the disks, distortion and tortuosity of the retinal veins, and hemorrhages on or near the swollen papilla. There usually is a sharp limitation of the condition to the optic nerve and to the retina immediately adjacent to the nerve head The degree of projection of the disk is determined by the difference in refraction between its most protruding part and the adjacent but unaffected retina This difference is expressed in diopters. The disk is not considered to be choked unless there is a refractive difference of 2 diopters or more. In the early stages of a choked disk the blind spot is enlarged As the intracranial pressure increases, the vision may become gradually less until finally blindness ensues. However, immediate relief of intracranial pressure prior to blindness often restores vision Choked disk may occur as the result of a number of intracranial conditions such as hydrocephalus, brain abscess and suppurative meningitis. It is important to keep in mind that choked disk accompanied with neuroretinitis is characteristic of malignant hypertension.

Choked disk does not accompany growths in the pituitary body. It occurs late, if at all, in lesions of the motor cortex, and is most frequent in neoplasms of the cerebellar parieto-occipital regions and midbrain. The condition is symptomatic of tuberculous, nontuberculous and suppurative forms of the meningitis.

Retrobulbar Neuritis. Inflammations of the optic nerve behind the eye are termed retrobulbar neuritis There is slight or no change in the appearance of the disk unless a tumor of the brain is present

The common cause of retrobulbar optic neuritis is syphilis. In rare instances optic neuritis may be caused by encephalitis, meningitis, acute febrile diseases, or by poisoning, especially lead. Retrobulbar optic neuritis may develop in young adults in association with disseminated sclerosis, without other symptoms. Diphtheria and diabetes may cause this disorder of the optic nerve. Unilateral optic neuritis occurs only when there is disease of the bones of the orbit or inflammation of the orbital tissues. It often exists without an assignable cause

The first symptom is unilateral or bilateral blurring of vision with pain in and above the affected eye brought on by ocular movements. The reduction of vision is rapid, reading is impossible within 2 or 3 days after the onset. One eye may be affected first, but the condition is bilateral

The pupils are equal and circular and react equally to light. They are sluggish Central vision is reduced or abolished. The visual field, except for the central scotoma, is normal. The optic disk at first is congested and shows haziness of the margins Temporal pallor then appears which bears no relation to the disturbances of vision Usually within a few weeks vision begins to improve Rarely is vision lost in the first attack There is a strong tendency for the trouble to recur.

Retrobulbar neuritis without edema of the disks is distinguished from that due to various poisons, such as lead, arsenic, thallium and methyl alcohol, as indicated by the history and appropriate examinations.

Neurosyphilis is not of etiologic importance Tumors of the hypophysis pressing on the intracranial portion of the optic nerve can be excluded on the basis of roentgenograms of the sella turcica

The prognosis of retrobulbar neuritis is at best doubtful, for complete recovery or for complete blindness Disseminated sclerosis may appear immediately or after many years When disseminated sclerosis develops in other parts of the nervous system, the process is acute and severe

Toxic Amblyopia. There are a number of causes for toxic amblyopia, among which quinine, methyl alcohol, overuse of tobacco, vitamin deficiency and uremia may be mentioned

The toxic amblyopias are manifested by a gradual diminution in acuteness of sight. The dimness of vision may be more definite in bright light than in dim light There are central color scotomata The ophthalmoscopic signs are usually minimal, but pallor of the temporal side of the disk, color scotoma, may occur as the condition progresses.

Atrophy of the Optic Nerve. Inflammation of the optic nerve, with congestion, hemorrhage and exudation into its substance, may affect the nerve posterior to the globe, *retrobulbar neuritis,* the nerve at its end, *papillitis,* the retina, *retinitis* In course of time there may be connective tissue proliferation and consequent atrophy of the nerve fibers, giving rise to secondary *optic atrophy*

Atrophy of the optic nerve occurs also as simple atrophy or primary atrophy, which is a noninflammatory condition. The cause is unknown There may be secondary atrophy of the optic nerve which is postneuritic, secondary inflammatory atrophy, or atrophy of nutritional origin

Primary Atrophy. In primary or simple optic atrophy there is degeneration of the nerve fibers The common causes of simple atrophy are cerebrospinal diseases, especially tabes dorsalis during its inception. Simple atrophy is less frequent in general paralysis of the insane It may occur in multiple sclerosis. When it does occur as a part of multiple sclerosis, it follows retrobulbar neuritis; it rarely results in complete blindness though often there is a transient blindness Simple optic atrophy may accompany systemic syphilis, malaria, diabetes, acromegalia, oxycephaly, profound hemorrhage with loss of consciousness (anoxia), the specific fevers, arteriosclerosis and certain poisonings, including methyl alcohol, lead and arsenic poisoning. It results from a *thrombosis of the central retinal arteries,* and it may occur in connection with choroiditis, retinitis, glaucoma, aneurysm of the internal carotid artery and orbital inflammation There is a hereditary form of the disease which is commoner in young men than in others.

Secondary Atrophy. Secondary optic atrophy is usually consequent to an optic neuritis, expanding intracranial lesions, and tumors of the optic nerve. Retrobulbar neuritis, syphilitic chorioretinitis, and retinitis pigmentosa may also be responsible for atrophy In some who have chronic hydrocephalus a greatly distended third ventricle may press on the chiasm and produce optic neuritis and atrophy.

Optic Atrophy and Arteritis. An optic atrophy may result from an arteritis as in periarteritis nodosa or in the condition known as temporal arteritis

Syphilitic Optic Atrophy. Bruetsch observed the existence of both the inflammatory and the degenerative phases of syphilitic optic nerve atrophy. He emphasized that the degenerative changes in optic atrophy are preceded by an inflammatory exudative phase. Visual field defects may be caused by the exudative processes in the marginal zone before atrophy of the nerve fibers has taken place, and such defects may improve or disappear after antisyphilitic treatment. Klauder and Meyer have stressed the necessity of an early ophthalmologic and perimetric examination of all patients who have neurosyphilis regardless of whether the serologic reactions of the blood and spinal fluid are positive or negative. The presence of pupillary abnormalities calls for examination of the cerebrospinal fluid in order to exclude optic nerve atrophy. It appears, therefore, that the problem of syphilitic optic nerve atrophy as a cause of blindness is concerned principally with early diagnosis. The ophthalmoscope and perimeter are as essential as the spinal puncture in the diagnosis and management of syphilis and its complication, primary optic nerve atrophy

In optic atrophy from any cause the patient complains of a profound disturbance of vision consisting of, on examination, a contraction of the visual fields, blind spot enlarged, color fields reversed, and scotoma.

INJURIES TO THE EYE FROM CONTUSIONS AND RADIANT ENERGY

There is no part of the eye which may not be injured so seriously by contusion or radiant energy as to diminish vision. In some cases the changes are progressive. In all cases a guarded prognosis should be given when these injuries have been sustained

Contusions. A contusion may vary in severity from a small abrasion of the cornea to rupture of the eyeball

Cornea. Injuries to the cornea incident to sharp objects, manifested by only a slight abrasion revealed by staining with fluorescein, heal immediately. A similar small abrasion of the cornea incurred by a sudden fall or a stroke from a blunt instrument causes severe pain The pain is increased on moving the lids, there is much lacrimation as well as reflex blepharospasm The sequence of events, a fall, slight corneal abrasion, and severe pain, is originated by a pre-existing corneal ulcer or results from injury to the fifth cranial nerve at the time of the fall or from pre-existing disease of the fifth cranial nerve.

In some instances of injury to the fifth cranial nerve the corneal abrasion may heal quickly. However, after days, weeks or even months acute pain and lacrimation commence. These symptoms are more evident on first opening the eyes in the morning than at other times. There is no doubt that in these cases the epithelium is abnormally loosely attached to Bowman's membrane, and is likely to be torn off by the lid on waking Such looseness of epithelium and formation of vesicles are characteristic of lesions of the fifth nerve and it is probable that recurrent erosion is due to this cause.

On examination deep opacity may be found which is due to accumulation of lymph in the interlamellar spaces These opacities are generally transient and clear up

Examination by means of the slit lamp reveals that all contusions of the eyeball are followed by the deposition of uveal pigment on the posterior surface of the cornea. There may be ruptures in Descemet's membrane, owing to its elasticity, but ruptures of the cornea are rare

Sclera. Rupture of the globe is generally due to its being suddenly and violently forced against the orbital walls. It is often due to falls or to the eye being forcefully struck by a projecting object, the force having been applied from the inferolateral direction, where the eyeball is least protected by the orbital margin. The wound is oblique, being farther forward internally than externally. It is situated concentrically with the corneal margin The conjunctiva is usually left intact, but severe injuries

to other parts of the eye are inevitably present. The iris is often prolapsed or torn away (iridodialysis) or retroflexed. The lens may be expelled from the eye or may escape under the conjunctiva, or be forced back into the vitreous. A displaced lens leaves the anterior chamber deep The anterior chamber contains blood and there may be hemorrhage into the vitreous. Detachment of the retina may occur, with or without subretinal or subchoroidal hemorrhage. The eye shrinks and sight is lost.

Iris. Most injuries to the iris caused by contusion are due to direct blows with a sudden inward displacement of the cornea.

Traumatic mydriasis may follow a contusion The pupil is immobile, and remains moderately dilated and paralyzed to accommodation permanently. Radiating lacerations of the iris, sometimes extending to the ciliary margin, may occur. In iridodialysis a black biconvex area is seen at the periphery, and the pupillary edge bulges inward With the ophthalmoscopic mirror a reflex can be obtained through the peripheral gap. Iridodialysis is permanent Apart from other injury, however, it rarely causes serious disability.

Lens. Injuries to the iris may cause rupture of the suspensory ligament. The lens is forced back into the vitreous. With the pupil dilated, the edge of the lens may be seen as a gray convex line by oblique illumination, but more readily as a black line with the ophthalmoscopic mirror The lack of support to the iris is detected by its unsteadiness, revealed on movement of the eye

In partial rupture of the suspensory ligament there is astigmatism which is much increased on movement of the head as the lens is thus tilted. Total dislocation of the lens into the vitreous causes a deterioration of vision

In a lens displaced so much laterally that the edge crosses the pupil, uniocular diplopia is present In subluxation the lens is likely to become opaque, owing to malnutrition The pressure of the edge of the lens on the back of the iris and on the ciliary body often originates a severe iridocyclitis and endangers the other eye by sympathetic ophthalmia Secondary glaucoma is frequent

With or without dislocation of the lens, concussion cataract occasionally follows a contusion In most of these instances the capsule has been ruptured The lens gradually becomes opaque The cataract spreads throughout the cortex until the appearance of a mature cataract is present

Vitreous. Hemorrhage into the vitreous is common after contusion. The vitreous chamber may be filled with blood and the eye is without reflexes On oblique illumination a dull red hue may be seen The blood may become almost completely absorbed, but cloudy opacities remain

Choroid. Rupture of the choroid occurs as the result of severe contusion It has also been caused by a bullet passing through the orbit behind the eye. Immediately after the injury the view is obscured by extravasation of blood When the blood has become absorbed, the rupture appears as a curved white streak over which the retinal vessels pass If the choroid is ruptured near the macula, there is loss of central vision. Ruptures of the choroid in which the macula is not involved cause little impairment of vision.

Retina. Detachment of the retina may be due to contusion However, spontaneous detachment of the retina often occurs

Blows on the eye may change the normal bright red color of the retina to a light gray near the papilla This change in color, which is probably due to edema, disappears after some days, and vision is usually restored to normal In some instances vision may be good at first but then central vision diminishes, and pigmentary deposits develop at the macula Hence prognosis should be guarded in all cases of serious blows on the eye.

Optic Nerve. The optic nerve is frequently injured in fractures of the base of the skull. Injuries by sticks or knives penetrating the orbit are rare. Avulsion of the

optic nerve is extremely rare but occurs as the result of wounds from flying missiles or bullets.

Radiant Energy. Radiant energy may be divided into two types: (1) the electromagnetic radiation and (2) the corpuscular radiation consisting of subatomic particles, the most noteworthy of which are the electrons (variously called beta rays and cathode rays, depending on their source) and the neutrons (Cogan).

The radio and diathermy waves cause no effect on the eyes except in the immediate vicinity of a transmitter. An electric current consisting of beamed movements of electrons may cause ocular injury or other injury through electrolysis or by the production of heat in the tissue.

The long infrared radiation which may give rise to cataracts is largely derived from open furnaces used by professional glass blowers and foundrymen Infrared cataracts occur only after exposure to intense heat for many years The cataracts resulting from infrared radiation are characteristically posterior cortical, forming at first saucer-like opacities belonging to the general group of so-called cataracta complicata.

The short infrared radiation which has been harmful to the eye (retinitis) may be obtained from electric arcs, the sun, and quartz and mining lamps.

The amount in the abiotic range of ultraviolet radiation filtering through the atmosphere from the sun is too slight to be harmful except under extraordinarily clear conditions or at high altitudes.

Keratitis resulting from ultraviolet radiation of the sun occasionally occurs with prolonged exposure at high altitudes or in the presence of large snow fields. The lesion consists predominantly of punctate erosions of the epithelium in the exposed portions of the cornea. The symptoms come on after a latent period of 5 to 12 hours; the patient has no feeling of ill effects from being exposed to harmful radiations at the time of exposure The effects are cumulative during an interval of 24 hours and, unlike the skin reaction, no tolerance is acquired by repeated exposures The patient's symptoms are severe photophobia, pain, epiphora and blepharospasm which are incapacitating at the time but seldom lead to permanent injury of any part of the eye.

The corneal lesion resulting from grenz rays and beta rays is keratitis with severe symptoms consisting of epiphora, foreign-body sensation and photophobia, but the latent period is longer and the duration is longer than is the case with ultraviolet effects Susceptibility of the lens to roentgen rays is said to be an inverse function of age, the most vulnerable being fetuses irradiated in utero

Glaucoma may follow roentgen irradiation of the eye. It arises several weeks after irradiation and usually in association with uveitis

The latent period for the development of cataracts following irradiation is usually from 6 months to 2 years but may be as long as 10 or more years. In general the greater the dose the shorter the latent period

A roentgen-ray cataract begins characteristically as an opacity at the posterior pole of the lens It may remain stationary but is usually progressive Progression is usually indicated by the appearance of vacuoles in the anterior cortex and an anterior subcapsular haze from proliferation of the lens epithelium

Cataracts from gamma rays and neutrons are similar to those produced by roentgen rays as regards latent period and structure, and similarly occur with doses that produce no other clinically evident abnormality

Radio waves are not known to produce any physiologic or pathologic effects on the eye, and the effect of diathermy waves is that of a thermal coagulation when locally applied

The long, or far, infrared rays probably can cause a thermal burn of the retina The susceptibility to retinitis may be influenced by nutritional factors which induce a sensitization to visible radiations so that retinal lesions may result from exposure to sunlight (Cogan)

VISION

The disorders of vision which are of diagnostic importance are hemianopsia, alterations in the color fields, amblyopia, and amaurosis.

Minor Disorders. If objects seen have a yellow tint, it may be due to jaundice or the administration of drugs, particularly of santonin. In exhausted neuropathic women or children overuse of the eyes may cause everything to appear red. The small, beaded, semitransparent threads or dots (muscae volitantes), seen in looking at some clear expanse of light, are, as stated, of small diagnostic importance. They appear to be most abundant in hysteria and functional disorders. Flashes or small luminous points of light before the eyes occur commonly after quick changes in position, coughing or straining, and usually are not of diagnostic import. However, they may constitute the aura of epilepsy or migraine Migraine may be preceded by scotomata resembling a cloud, the edges of which are brilliantly lighted or colored The scintillating scotomata appear as bright dots, whirling figures and as bright lines before the eyes

Failing Vision. The causes of failing vision arise from the cornea, iris, ciliary body and choroid, retina, optic nerve, lens and vitreous, and from disuse. The following paragraphs contain a summary of the views expressed by Post in regard to failing vision

Among the corneal causes of visual failure, tuberculosis is common. It is usually considered an allergic manifestation. Corneal degeneration is frequent in old persons. The central areas, anteroposteriorly, may become less transparent. Nodules appear in the posterior elastic membrane that look like small drops of water on the rear surface of the cornea when seen with the corneal microscope. Epithelial degeneration occurs

Corneal ulcers are an important cause of visual failure. They occur throughout life, their causes varying from gonorrhea in infancy through phlyctenular keratitis in youth to malnutrition and the physiologic changes incident to age. In preadolescence the interstitial keratitis of syphilis may cause blindness.

Allergic diseases of the iris, ciliary body and choroid are as frequent in ophthalmologic practice as allergic diseases of other structures are in every other department of medicine Allergic diseases of the eye are chiefly conjunctivitis and lid reactions, the former the so-called vernal conjunctivitis, and as such they are seldom responsible for failing sight, but allergic scleritis and uveitis are important causes for gradual loss of vision.

In tuberculosis, sections of the lesions in the uveal tract seldom reveal the tubercle bacilli

The most serious form of uveitis is sympathetic ophthalmia, which is probably due to sensitivity to uveal pigment Differential diagnosis of allergic uveitis depends on the presence of the inherited allergic state, the elimination of other more easily identifiable inflammations, such as leprosy, syphilis and sympathetic diseases, and finally identification of the offending antigen by means of allergy tests.

Retinal causes of diminished vision are numerous Diabetes affects the eye late in the course of the disease, particularly in the form of chorioretinitis, though undoubtedly some cataracts have diabetes as their cause Diabetes may be the cause of [illegible] it has started

[illegible]

Often the first ocular symptom is visual failure, and when this occurs the chorioretinitis is severe. It may take place in patients in whom the diabetes is under control. The usual therapy for diabetes is completely ineffective with respect to established retinal lesions.

In cardiovascular-renal disease both sudden and gradual visual loss occur. The former is especially associated with large retinal hemorrhages and the latter with arteriosclerosis and small hemorrhages and exudates. The eyegrounds reveal the changes of malignant hypertension as early as these changes are to be found anywhere in the body.

Degenerative changes frequently accompany old age. The retina suffers in this condition primarily from malnutrition and probably an accumulation of waste products. Glaucoma causes a failure of vision

Optic atrophy is a major reason for failing sight. Among its most important medical causes are syphilis, hypophyseal tumor, multiple sclerosis and drugs. In these diseases the ophthalmologist is often the first to make the diagnosis. In 8 of each 10 patients who have supratentorial neoplasms, choked disks are present, whereas in those who have hypophyseal tumors atrophy of the papillomacular bundle is the rule. In multiple sclerosis the onset may be associated with optic neuritis, but more often there is simply temporal pallor of the nerve head with loss of central vision.

Failure of sight from optic atrophy may be sudden, as from poisoning from drugs such as methyl alcohol (CH_3OH) (see Methyl Alcohol, Chapter 19).

Peripheral field changes may be advanced before they attract the patient's attention, as for instance in chronic simple glaucoma, the most frequent cause of failing vision and blindness of middle and old age. This disease may not cause pain or redness of the eyes and is noticeable only to a discerning patient by a diminution in the visual field or halos about lights. Cataracts are common, and their role in failing vision is well known.

Congenital Color Blindness. Congenital color blindness or congenital color amblyopia occurs in 3 or 4 per cent of boys and men and in about 0 3 per cent of girls and women The condition generally affects both eyes and is often hereditary. The functions of the eyes are otherwise normal There are a number of tests for color vision which are particularly useful in the examination of employees in certain occupations in which perfect color perception is essential, for example in railway, steamship and aviation services as well as in motor driving. In transportation services the most commonly used signals are red and green, the colors in which most color-blind persons are defective.

There are a number of well-known tests for color vision· Stilling's test, Ishihara's test and Holmgren's test

The Holmgren test is frequently used, and is very convenient It employs a large assortment of colored worsteds This collection includes (1) test colors: pale green, light pink and bright red, (2) match colors lighter tints and darker shades of test colors and (3) confusion colors. yellow, brown, gray, drab, fawn, mauve, pale blue and the like. The test is performed in good daylight. The pale green sample is given to the individual, who is asked or required to select colors that match the test sample If he does this correctly, he has normal color sense If he not only fails to select similar colors but also confuses colors and in addition shows a certain hesitancy, his color sense is defective. Next a pink skein is selected and the person being examined is asked to match it. If, besides similar skeins, he selects blue or violet, he is red blind If he selects green or gray, he is green blind Finally he receives the bright red test skein for matching. If besides red, he chooses green and brown colors, darker than the red, he is red blind. If he selects shades of those colors lighter than the red he is green blind

Effect of Teaching on Color Blindness. Some men can be taught how to correct for color blindness Educational programs for those who are color blind have been conducted which permit them to pass tests for color blindness In one technic (Lepper) the subjects are instructed to get someone with normal color vision to assist them and to trace the shapes of the figures carefully even in those charts in which they can see the figures fairly well. They are instructed to continue working on harder and harder charts. Thus the person concerned builds a learning curve and with sufficient time seems to master the color manual It seems quite likely that those who have disturbances of color vision do fix in their minds appearances which are associated with certain colors when viewing objects that have for them some familiarity.

Alterations in the Field of Vision. The alterations in the size and shape of the visual fields which may be of value in diagnosis are hemianopsia, contraction of the visual fields for light, and contraction of the color fields. In connection with hemi-

anopsia, blindness due to disease of the optic nerve or its central connections is diagnostically important.

The diseases which may affect the optic tract are neoplasms, syphilitic meningitis, gummas and tuberculous meningitis. In these cases the crus may be implicated, causing hemiplegia or, as the result of basal lesions, ocular muscle paralysis may be present. The absence of any form of aphasia in right hemiplegia is against a central lesion and in favor of an affection of the optic tract

Hemianopsia. A condition termed hemiopia, hemianopia or hemianopsia is blindness of one half of the field of vision.

Since in the majority of cases of hemianopsia there is organic disease of the brain, hemiplegia and hemianesthesia on the same side with the hemianopsia are uncommonly associated symptoms; and, in left-side lesions, aphasia. If athetosis coexists with lateral hemianopsia, it is significant of a lesion involving only the posterior gray mass of the optic thalamus. If the hemianopsia involves a quadrant and not a semicircle, or is otherwise incomplete, and if mind blindness or word blindness coexists, the lesion is usually cortical. Dimness of vision in one eye, and a marked contraction in the visual field of the other, together with mind blindness (seeing but not recognizing objects), is a combination indicative of a lesion of the angular gyrus.

Hemianopsia in rare instances may be due to hysteria, in which case the conjunctiva is usually anesthetic and hemianesthesia is present. But by far the commonest alterations of vision in hysteria are contraction of the visual fields and changes in the color sense. The ophthalmologist can usually definitely distinguish the contraction of the visual fields due to hysteria from those due to organic disease.

Total blindness of one eye may be due to a lesion of one optic nerve, or disease of one occipital lobe, and if in addition there is hemianopsia of the opposite eye, it may be due to disease of the decussating fibers in the center of the chiasm together with the direct fibers of one lateral angle If there is no disease of the retina or other ocular structures sufficient to account for the loss of sight, a lesion at the decussation is likely to be present Total blindness of both eyes will be caused by disease affecting the entire chiasm, or bilateral lesions of the cuneus.

Hemianopsia, or blindness of one half of the visual field, is of different varieties and, together with the qualifying terms employed, the name refers to the field of vision from the point of view of the patient—not to the retina. Thus right temporal hemianopsia means that the outer or temporal half of the field of vision of the right eye is blind, so that if the eye is fixed on a point directly in front, objects to the right of the point of fixation will not be perceived. Therefore, remember that blindness of the temporal half of the field of vision is due to loss of function of the inner or nasal half of the retina, because of the crossing of the light rays in the media, and so with other varieties.

If the hemianopsia affects both visual fields, it is *bilateral*, if corresponding halves (both right or both left) are implicated, it is *homonymous* or lateral If both temporal or both inner fields are implicated, it is *heteronymous*. Furthermore, the inner fields are termed *nasal;* the outer, *temporal*. Very rarely the upper or lower halves of the visual field are effaced and if so, the condition is then called superior or *inferior* hemianopsia Hemianopsia may be partial, only a portion of the half field being blank. The unaffected half may retain its normal dimensions or, as in some cases, be reduced in size.

The presence of hemianopsia may be detected by those untrained in ophthalmology, but delineation of these defects is a task for the ophthalmologist To detect the presence of hemianopsia, each eye must be tested separately, the resting eye having been covered by a card. The patient, being placed with his back to the light, is told to fix the uncovered eye on that part of the physician's face (placed about 2 feet (61 cm.) away) which is most nearly on the horizontal plane of the eye to be

ested. The finger or a bit of white paper is then brought, first from one side, then rom the other, to the median line. If the patient cannot see the paper until it has assed nearly or quite to the line of fixation, hemianopsia exists. The vertical extent of the field is tested in a similar manner by bringing the object from above downward and from below upward

The diagnostic indications of the various forms of hemianopsia are as follows·

UNILATERAL NASAL HEMIANOPSIA. Blindness of the nasal half of the field, an extremely rare occurrence, indicates a very limited lesion at the outer angle of the chiasm.

BINASAL HEMIANOPSIA. Also rare is blindness of the nasal half of both fields, requiring for its manifestation two symmetric lesions, of both outer angles of the chiasm, or the outer sides of both optic nerves

BITEMPORAL HEMIANOPSIA. Blindness of the temporal halves of both fields is produced by a lesion involving the anterior angle or central portion of the chiasm.

The disease (affecting the chiasm) which is most frequently responsible for the three preceding varieties of hemianopsia is tumor or enlargement of the pituitary body, with which may be associated diabetes insipidus, proptosis and a flow of fluid from the nostril Other causes are tubercles, tumors, cysts, basilar meningitis, periostitis, exostosis, fracture of the body of the sphenoid bone, and gumma The last may give rise to evanescent recurring hemianopsia. When the chiasm is affected, the lesion is likely to be progressive, and gradually involves both crossed and uncrossed fibers, thus causing total blindness of one or both eyes, according to the extent of the destruction. Lesions of the chiasm may be attended by symptoms indicating involvement of the olfactory and trigeminal nerves and of the nerves of the ocular muscles, namely, anosmia, anesthesia of conjunctiva and cornea, and ocular paralysis

RIGHT OR LEFT LATERAL (HOMONYMOUS) HEMIANOPSIA Blindness of the right or left half of both fields is significant of a lesion situated at some point between the chiasm and the cortical center in the occipital lobe, namely, the optic tract, the pulvinar or posterior gray mass of the thalamus, the anterior corpora quadrigemina, the fibers passing from the thalamus and corpora to the occipital lobe either in the internal capsule or the optic radiations, or the cortical center itself

Contraction of the Visual Fields for Light. In order to determine the presence of this symptom, the examiner invokes the aid of an ophthalmologist and his perimeter, as it cannot be ascertained by any less accurate test. Leaving out of consideration glaucoma, optic atrophy or other organic disease, by far the most important indications of a nearly uniform contraction of the visual fields relate to the presence of hysteria and traumatic neuroses.. As a rule, one field presents a greater contraction than the other. In neurasthenia, while there may not be a true concentric limitation of the visual field, yet the fatigue of continued testing will sometimes develop a decided temporary diminution in its size

Contraction of the Visual Fields for Color. The color fields are tested by the perimeter, using bits of colored paper Passing from the circumference to the center of the field, the perception of white objects is found to have the widest extent. A little nearer, blue is perceived, then red, then green

Limitation of the color fields is a common symptom in hysteria and traumatic neuroses Sometimes a transposition of the normal fields for different colors will occur. Like vision in general, the color perception may be much reduced or abolished by optic neuritis or atrophy.

Amblyopia and Amaurosis. *Amblyopia* is a reduction in the acuteness of vision, a dimness or partial blindness, and cannot be relieved by glasses The condition is not dependent on any visible changes in the eye. *Amaurosis* is a total loss of

ns of partial
the centers
appearance
most cases,
temporary.

Obstruction or thrombosis of the central artery causes a sudden loss of vision, commencing at the circumference of the visual field and extending to the center. It

is frequently indicative of cardiac or vascular disease, namely, bacterial endocarditis, valvular disease, particularly mitral stenosis, atheroma of the large arteries, aneurysm of the aorta, and thrombosis of the pulmonary vein; very rarely it occurs in rheumatic fever and chorea. In a very small proportion of cases the sudden loss of sight in chronic nephritis is said to be due to this accident or to separation of the retina

The most frequent causes are uremia, diabetes, and certain drugs, large hemorrhages, migraine and hysteria When occurring in uremia, loss of sight ordinarily follows coma or convulsions, is sudden and usually lasts but 1 or 2 days. Quinine and the salicylates may cause sudden amaurosis, and it sometimes occurs in alcoholism Severe hemorrhages, particularly those from the stomach, may be responsible for a sudden failure of sight Migraine may exhibit as one of its symptoms a fugitive blindness, perhaps of only one half the visual field (hemianopsia). The amaurosis of hysteria is associated with emotional states and other characteristic symptoms, and no matter how complete the apparent loss of sight may be, the pupillary reflex, both direct and consensual, is retained

Hysterical amblyopia usually affects young girls and women and occasionally boys and young men. This form of amblyopia is most often bilateral, but it may be unilateral. The most constant symptom is reduction in vision amounting to complete blindness The field of vision is contracted concentrically both for white and for colors The pupillary reflexes and ophthalmologic examinations reveal no abnormalities

Simulated amblyopia is a resort of malingerers, who frequently pretend various degrees of loss of vision in one or both eyes in attempts to recover damages for lesser injury The tests for simulated amblyopia are difficult to perform, because the claimant often has been coached in the various devices of evasion, such as closing one eye and then the other during the test in order to ascertain which eye is being examined The ophthalmologist is aware of all of these difficulties.

Blindness in both eyes is more difficult to detect than blindness in one eye Contraction of the pupil to light is presumptive evidence of some sight, but in rare instances the pupils react to light in total blindness In malingering, when a claim of blindness is made, the ophthalmologist, by the use of special tests with lights and prisms, can detect evidences of eyesight

Night blindness or *nyctalopia* is a condition in which the sight is good by day, but deficient at night Sometimes there is a history of exposure to bright light. It may accompany certain forms of atrophy of the optic nerve such as that manifested by retinitis pigmentosa Night blindness may result from a deficiency of vitamin A. Xerophthalmia is often present at the same time

Hemeralopia is a condition in which the patient sees better in an obscure light than in bright sunlight

Ocular Manifestations of Malaria. Malarial amblyopia occurs as a result of the action of the malarial toxin on the optic nerve and retina Often optic neuritis and papillary edema result from the blocking of the retinal and choroidal vessels by parasites and leukocytes. The retinal hemorrhages are usually small, multiple and peripheral; large macular hemorrhages do occur in the malignant types of malaria. Ulceration of the cornea is a common ocular sequela of malaria, and recurrent iritis is frequently associated with this keratitis. The complaints are loss of vision, frequent headaches in the occipital and temporal regions, dizziness, pain in the eyeballs, tenderness on palpation, photophobia, lacrimation, and spots before the eyes

The objective findings are irregularity of the pupils, retinitis of the atrophic type, usually in or around the macular area, unusual concentrations of choroidal pigmentation, generalized hyperemia of the retina and nerve head, optic neuritis both mild and severe, optic atrophy, and in a few cases a severe progressive chorioretinitis and uveitis

Refraction and Errors of Refraction. In the normal eye light passes through media of different densities, being refracted at the surfaces of junction of the media so

that the incident ray comes to focus on the retina. This condition is termed emmetropia.

If the incident parallel rays come to focus anterior to, or before they reach, the retina, the condition is known as myopia or nearsightedness.

In hyperopia, hypermetropia or farsightedness, there is a lack of refracting power sufficient to bring to focus the incident or parallel rays of light on the retina.

Myopia. The common cause of myopia is an abnormally long anteroposterior diameter of the eyeball which results in the condition termed axial myopia. Curvature myopia results from aberrations in the curvatures of the refracting surfaces of the cornea and lens which bring the incident light rays to a premature focus Abnormal positions of the lens may create similar difficulties. Myopia may arise when the refractive indices of the cornea, aqueous humor or the lens are changed significantly.

Myopia is rare in the newborn, but its incidence increases rapidly until the age of about 20 years is attained Its incidence has no relation to any uses of the eye, but excessive use of a myopic eye is deleterious. The cause of myopia is some predisposition which provides the requirements for myopia to develop.

In myopia a crescentic posterior staphyloma (myotic crescent) in the fundus of the eye is present and this development is seemingly of congenital origin. This sort of staphyloma is associated with some distortion of the papilla.

In mild or low myopia there is indistinct distant vision. In more severe or high myopia there is indistinct vision and discomfort after near work as the result of disproportion between the efforts of accommodation and convergence. The eyes are sensitive to light Black spots are seen floating before them, and sometimes flashes of light are noticed. Flashes of light before the eyes are often a symptom too of detachment of the retina In very high myopia the eyes are prominent, the pupils are large, and the anterior chamber appears deeper than normal, probably only owing to the dilatation of the pupil. There may be an apparent convergent squint. A true divergent strabismus may be found, either concomitant or affecting only one eye. Vision may be very poor, even with correction, scotomas may be present, both central and peripheral

The ophthalmologist usually reports normal findings on ophthalmoscopic examination of the myopic eye In moderate myopia there is a myopic crescent. If there is a high error of refraction, a posterior staphyloma is recorded, often with a change in the course of the retinal vessels, and degenerative changes in the choroid—a chorioretinal atrophy There may be described hemorrhages in the macular region. Vitreous opacities and a black spot at the fovea may be present Detachment of the retina is likely to occur in a myopic eye

With a refractive error of up to 5 or 6 diopters myopia, unless in children of preschool age, has a good prognosis If there are 10 diopters or more of myopia the prognosis is not good Serious retinal damage or detachment of the retina is likely to ensue

Hypermetropia (*Hyperopia*). Hypermetropia is almost always present in the infant Its incidence decreases rapidly during the first two decades of life.

In many, especially the young, with ample reserve powers for accommodation there are no symptoms unless the condition is extreme. When the powers of accommodation are insufficient from any cause, there ensues eye strain. The eyes, after use, ache, feel dry and require excessive blinking. Rarely there may be lacrimation

In aging persons the far point is beyond the range of comfortable reading The print has to be held farther away than usual in order to read at all. In the aged the hypermetropia is index hypermetropia and much of the deficient vision may be due to an increased refractive index at the cortex of the lens.

The conjunctivae and edges of the lids become reddened. Headache, often frontal, follows excessive use of the eyes. Ophthalmoscopically the fundus may exhibit no abnormality A bright reflex is commoner in hypermetropic than in

emmetropic or myopic eyes. The inferior crescent and an abnormal tortuosity of the retinal vessels are common in hypermetropic eyes. In some cases there is a pseudopapillitis

Astigmatism. Astigmatism is present when there is defective curvature of the refractive surfaces of the eye as a result of which a ray of light is not sharply focused on the retina. The light is spread over an area of the retina and not brought to a focus on a spot of the retina. There are many varieties of astigmatism. Each variety is named according to its causation by prefixing an appropriate adjective or adjectives for instance, corneal astigmatism, which is due to irregularity in the curvature or refracting power of the cornea.

Regular astigmatism designates the condition in which the refractive power of the eye shows a uniform increase or decrease from one meridian to another, being practically constant in each meridian, and the image produced is regular in shape, either a line or an oval or a circle

Regular astigmatism is likely to cause the worst forms of asthenopia or eye strain, the asthenopia in these cases is only in part accommodative. It is often worse in the lower degrees of astigmatism than in the higher. Aching of the eyes, severe headaches and migraine are matters for complaint. The eyes become fatigued easily. The letters of print run together

Anisometropia. A slight anisometropia is almost the rule. It is a condition in which the refraction of the two eyes shows a difference. In mild forms of anisometropia binocular vision is imperfect In high-grade anisometropia binocular vision can be obtained only by the use of correct lenses. Distinct vision, even with correction, may be only uniocular and the eye which is not in use may become divergent In some instances if one eye is emmetropic, the other myopic, the emmetropic eye may be utilized for distant vision and the myopic eye is used for near vision.

Anisometropia is usually of congenital origin. The symptoms are variable and may not be noticeable to the child

TOPOGRAPHY AND REGIONAL DIAGNOSIS OF DISEASES OF THE NECK

The neck, by means of the cervical vertebrae and muscles, elevates the head and allows it to be moved freely in different directions. It is interposed between the portals of entry to the respiratory and the digestive system and the thoracic organs. It is therefore subjected to secondary invasions by the agents of infectious diseases as well as the extension of malignant processes from both directions. In addition the neck may be involved in disease arising in its own organs. Some of the diseases are of congenital origin. The majority of the congenital diseases, such as branchiogenic and thyroglossal duct cysts, are remnants of vestigial organs.

In this portion of the text are considered the structures of the neck in the median line, those regions, or triangles, on each side, anterior to the sternocleidomastoid muscle, those posterior to this muscle, between it and the trapezius (Fig. 5-1), and finally the air passages.

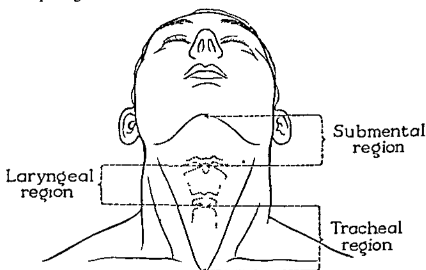

Fig 5-1 Median regions of the neck

REGIONS OF THE NECK

Median Portion. Viewed from in front, the median portion of the neck may be divided into three regions, submental, laryngeal and tracheal

The *submental region* extends from the chin to the lower border of the body of the

The *tracheal region* extends from the lower edge of the cricoid cartilage of the sternum. Just above the sternum, between the sternal origins of the sternocleidomastoid muscles, is the suprasternal notch. Laterally the region is limited by the sides of the trachea.

Triangles of the Neck. The ventral and lateral aspects of the neck are divided into anterior and posterior primary triangles by the sternocleidomastoid muscle. The base of the anterior triangle is the border of the jaw, and of the posterior triangle the clavicle. The anterior cervical triangle is secondarily divisible into three small triangles: the *submaxillary*, between jaw and digastric muscle; the *superior carotid*, bounded by digastric, ... *rior carotid* (or muscular) *tri-* ... rior cervical triangle is divided ... *ccipital* and *omoclavicular triangles*. Each of these triangles is at times further subdivisible into minor regions (Fig. 5-2).

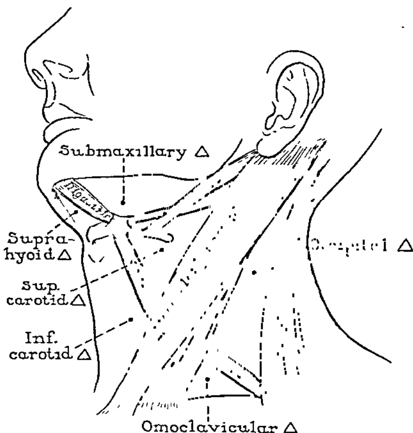

Fig 5-2 Triangles of the neck.

STRUCTURES TO BE FELT IN THE MEDIAN LINE

Some necks are short and stout, others are medium in length and thickness, others are long and thin, and there are many gradations between these types. For this reason it sometimes may be easy, sometimes difficult, to identify the structures.

On palpating downward from the symphysis of the mandible, the finger discerns a hollow. On pressing into this hollow, the finger rests between the digastric muscles on each side and on the mylohyoid muscles beneath. Still deeper than the mylohyoid muscles are the geniohyoid and geniohyoglossus muscles attached to the genial tubercles on the inner side of the mandible. If the lymphatic nodes at this point are enlarged, they can be felt

The hyoid bone is next and it can be readily felt in the median line. If it is not easily discovered in the median line, it can be felt by a finger and thumb placed on each side of the neck above the thyroid cartilage.

Passing over the hyoid bone, the finger sinks into the space between the hyoid bone and the top of the thyroid cartilage. Next comes the thyroid cartilage or Adam's apple. This structure can readily be seen in adult males and in thin persons of either sex. Despite obesity it can always be felt. The finger then sinks into the space between the thyroid cartilage above and the cricoid cartilage below.

From the cricoid cartilage, which is on a level with the sixth cervical vertebra, down to the sternum only soft structures can be felt. The sternum projects forward and the trachea inclines backward so that opposite the top of the sternum the trachea is about ¾ inch (2 cm.) behind the sternum. The distance between the top of the sternum and the cricoid cartilage in an adult male is about 1¾ inches (4.5 cm.) The trachea may be brought closer to the anterior portion of the sternum by overextending the head

If palpation is limited strictly to the midline, only the isthmus of the thyroid can be felt However, it is well to remember that the thyroid gland sometimes enlarges during menstruation and always somewhat during pregnancy, returning to the normal size during the interval

A tumor in close relations with the trachea, and moving with it during the act of swallowing, is an enlarged thyroid gland A solid, hard enlargement is usually a simple goiter, and the enlargement ordinarily is greater on one side than on the other Determination of the presence or absence of induration and of fluctuation, pulsation and systolic thrill and murmur is routine during physical examination of the gland

If fluctuation is present, the enlargement is in all probability a cyst, either of the thyroglossal duct or of the thyroid gland. If pulsation, thrill and murmur exist, the *case is one of exophthalmic goiter. If a diffuse enlargement with tenderness* is present, an acute or subacute thyroiditis is the cause.

Tumor or aneurysm in the root of the neck and behind the sternum may cause prominence of the thyroid

The thyroid gland in some conditions of disease undergoes *atrophy*. Often in myxedema and cretinism the thyroid is impalpable

Abnormal situation of organs in the neck often indicates disease; for instance, displacement of the trachea to one side or the other may be due to chronic fibroid phthisis, thoracic aneurysm, or mediastinal tumor. In pulmonary tuberculosis the trachea is drawn to the affected side by the shrinking lung. Aneurysm of the innominate artery pushes it to the left

Tracheal tugging is considered a valuable sign in cases of suspected mediastinal tumors or aneurysms In aneurysms it depends on the fact that the arch of the aorta curves back over the left bronchus, and if an aneurysmal dilatation of the arch is present, each systolic distention of the vessel presses down on the bronchus, thereby pulling the trachea downward

To determine the presence of tracheal tugging, if the patient is ambulatory, stand behind him and have him close his mouth and raise his chin The tips of the forefingers are then placed firmly on either side of the cricoid, pressing upward; then if a downward tug is present, it will be detected

MUSCLES OF THE NECK

The sternocleidomastoid muscle is the one muscle of the neck that lends itself for examination. If the patient is lying down, have him raise the head; or if sitting up, turn the head as far as possible to the right and left, with or without resistance offered by applying the hands to the sides of the head; or bend it forward against pressure on the forehead. If the muscle is not paralyzed, it stands out prominently (Fig. 5-3); nerve supply, the spinal accessory nerve (eleventh cranial nerve).

Torticollis or Wryneck. Torticollis or wryneck, a disorder in which the neck is so twisted that the face is turned toward the side opposite the contracted muscle

and looks somewhat upward, usually is caused by some disorder of the sternocleidomastoid muscle. The sternocleidomastoid is not always the only muscle involved, for the trapezius and others often are affected likewise, owing to an attempt of the other cervical rotators to sustain and relax the sternocleidomastoid and thus obtain physiologic rest for it. When the trapezius alone is involved, the head is drawn backward and toward the affected side.

Torticollis is congenital or acquired. The congenital form is caused by injury to the sternocleidomastoid muscle occurring at birth or to developmental defects of atlas, occipital bone or cervical ribs. A swelling or tumor may be present in the course of the muscle when the muscle has been injured at birth. In the acquired form the distortion may be more or less permanent and may be due to caries or other disease of the spinal column. In such cases it is evident that treatment is to be directed to the diseased spinal column rather than to the sternocleidomastoid muscle, which is found to be relaxed

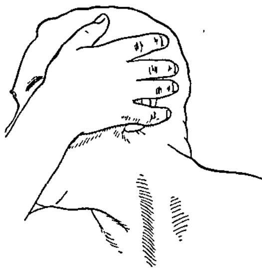

Fig 5-3 Sternocleidomastoid muscle Attempts are made to rotate the head against resistance Nerve supply, spinal accessory nerve (eleventh cranial nerve).

Inflammation of muscles, fascia or the lymph nodes of the neck may cause the patient to hold the head and neck in a distorted position, *wryneck*. The wryneck in such cases will disappear as the cause subsides Rheumatic affections, "taking cold in the neck," are a common cause of torticollis in which the sternocleidomastoid muscle may become contracted.

A chronic torticollis occurring in an adult may be conversion hysteria.

Spasmodic Disorders. *Nodding spasm,* a rhythmic nodding movement of the head and neck, may be a form of habit spasm. If nodding spasm is accompanied by a momentary loss of consciousness, the condition is epilepsy. Nodding spasm may be indicative of hysteria, either alone or as a part of a rhythmic or hysterical chorea (salaam convulsion). Pulsating shaking of the head seemingly arising in the neck is often seen in the aged, and occasionally in persons with aortic insufficiency.

Spasmodic jerking of the head, recurring every few minutes, in which the head is brought toward one shoulder, and at the same time the face is rotated to the opposite side and the chin raised, is the clonic form of spasmodic torticollis The shoulder may be simultaneously jerked upward to meet the head In chorea the movements of the head are by contrast extremely irregular and bizarre, and the facial muscles are affected before those of the neck.

DISEASES DUE TO PRENATAL INFLUENCE

Tumors of the Thyroglossal Duct. The vestigial rests of the thyroglossal duct account for some of the midline tumors of the neck. These tumors lie between the isthmus of the thyroid gland and the base of the tongue. Most commonly they occur either below or above the hyoid bone A remnant of the thyroglossal duct may end at the hyoid bone, but should it continue upward, it may pass in front of, through or behind the body of that bone.

Thyroglossal cysts are independent of the thyroid gland A cyst of the thyroglossal duct is manifested by a gradually developing, painless enlargement in the

front of the neck. If unsuccessful attempts have been made to remove the cyst, most can be learned from the history prior to surgical operation. Before there has been infection or surgical intervention, both the tumor and the skin over the cyst are movable.

Cysts occur also just beneath, within or on the dorsum of the tongue. When they are large, there may be disturbance of respiration as well as of deglutition. These cysts may become malignant.

Thyroglossal cysts may become infected and may suppurate from time to time, apparently healing completely, to discharge again in a few years without having been operated on. From such repetitions of suppuration, sinuses may result.

The exact diagnosis of cyst of the thyroglossal duct can be made only by microscopic study of the tissues

Branchiogenous Cysts and Fistulas. *Branchiogenous cysts* commonly occur in the upper part of the anterior triangle of the neck, just beneath the angle of the jaw. They develop slowly. In the beginning these tumors are benign but they may become malignant while yet of small size. In the early stage a branchiogenous cyst is not apparent unless the skin is stretched over it. A tumor of this type can attain a large size, displace the sternocleidomastoid muscle backward, and bulge in the floor of the mouth at the base of the tongue

Branchiogenous fistulas are persistent gill-cleft remnants remaining as ducts which extend from near the floor of the mouth to the skin in the region of the insertion of the sternocleidomastoid muscle around to the midline. The whole of the duct or only part of it may be persistent. If one of these fistulas is not patent at one end or at both ends, it is a cyst and is called a gill-cleft cyst.

There is a history that the tumor opened spontaneously or by incision and that since its opening there has been a draining sinus. There is a small inflamed tumor medial to the sternocleidomastoid muscle If a sinus is present, it may drain continuously or it may become closed for some time, to reopen anew.

When one of these fistulous openings is explored with a probe, it can be followed for varying distances in the direction of the floor of the mouth The probe may even pass the entire length into the oral cavity

The diagnosis is made by microscopic study of the tissue

Dermoid Cysts. Dermoid cysts are small midline tumors of the neck which appear under the chin The patient usually complains of a bulge under the chin like the chin of an obese individual These tumors often bulge into the floor of the mouth, or they may appear almost entirely within the mouth on each side of the tongue. Other situations in the neck for dermoid cysts are near the mastoid process, or the cysts may protrude from the mediastinum in the episternal notch.

Diagnosis is established by microscopic study of the tissues.

Angiomas. There are congenital hemangiomas and lymphangiomas of the neck

Hemangiomas occur rarely in the cervical regions They usually are situated in [illegible] ...ay be deeply set in the tissues and may not be [illegible] These tumors often do not increase in size, but [illegible] hemangiomas communicate with the venous system and consequently they are compressible, as soon as the pressure is removed they reappear Some of these tumors are large and produce extensive bulging over the lower part of the neck Generally, however, they are limited to the skin or to the superficial tissues

Diagnosis is established by the behavior of the tumor on application of pressure. The tumor disappears on pressure and returns immediately on release of the pressure.

Lymphangiomas are common lesions of the neck which often are situated beneath the lower jaw and gradually attain a large size, filling the entire side of the neck. They occur also in the supraclavicular fossae, and in the axillary and the

femoral regions Occasionally a lymphangioma may extend into the mediastinum. As a result of irradiation these tumors may appear to be diffusely inflamed and, under these circumstances, are difficult to differentiate from neoplastic disease.

The diagnosis is established by microscopic study of the tumor tissues.

LYMPHADENITIS OF THE NECK

One of the commonest affections of the neck is inflammation of the lymph nodes. The term lymphadenitis formerly was employed in descriptions of tuberculosis and syphilis. The term as used here includes all infections of lymph nodes.

The acute infections of the lymph nodes are caused by one or more of the pyogenic microorganisms, *Spirocheta, Borrelia, Treponema* or a filtrable virus. In the great majority of cases these acute infections of the lymph nodes subside and are designated as nonsuppurative lymphadenitis A nonsuppurative lymphadenitis is a regular concomitant of tonsillitis and other acute bacterial infections of the mouth. Enlarged lymph nodes from viral infections do not suppurate.

In infections of the mouth the lymph nodes in the drainage area of the mouth become enlarged and sensitive to pressure. The reaction of the lymph nodes is usually obscured by the reactions of the causative disease. The inflamed nodes may themselves produce general symptoms after the original causative lesions have subsided However, the manifestations of an acute lymphadenitis usually are limited to tenderness due to the inflammation of the capsule of the lymph node and to perinodal edema. If the infection is severe, the capsule of the node may be invaded, and if a number of nodes are involved, the inflammation may extend beyond the capsule so that the individual nodes cannot be made out

The situation of the involved nodes depends on whether the infection is situated in the mouth or in the throat The enlargement of the nodes may be progressive along the line of drainage; that is, first those near the site of infection enlarge and become tender; then they subside, to be followed by enlarged nodes in more remote regions The involvement of the lymph nodes in remote regions of the neck, or diffuse involvement, is usually indicative that infection is not in the mouth. Infection of the scalp, the fingers, arms and, occasionally, of the axilla may cause an enlargement of the lymph nodes in the neck At times it may seem that the acute inflammation of these cervical lymph nodes is going to terminate in suppuration, the edema and cellular induration having formed a diffuse mass, but almost always the lesions subside spontaneously

Acute Diffuse Lymphadenitis (Ludwig's Angina) Extension of the inflammation in an infected lymph node beyond the node or its capsule constitutes diffuse lymphadenitis Occasionally, diffuse lymphadenitis will develop in the neck as a result of some severe infection in the oral cavity, and this acute diffuse infection tends to follow the planes of the fascia in the neck This condition, if severe, is known as Ludwig's angina Ludwig's angina usually is confined to the floor of the mouth, and because the tissues become very hard and woody, the condition is known as woody phlegmon or ligneous phlegmon, which later extends to the neck. At times Ludwig's angina may be extremely acute and may terminate fatally within a very short period, 1 or 2 days.

Viral Lymphadenitis. Many of the viral infections and infectious mononucleosis are accompanied by preaural and cervical enlargement of lymph nodes

Chronic Lymphadenitis. The lymph nodes, subsequent to an acute or an unrecognized inflammation, may become chronically enlarged and be palpable as discrete nodules

In the presence of chronic lymphadenitis it is important to determine whether tuberculous infection exists and to differentiate it from other types of chronic lymphadenitis The beginning of tuberculous lymphadenitis is usually in the superior

triangles of the neck There is no acute onset. The nodes become enlarged slowly.

Tuberculous Lymphadenitis. Tuberculous lymphadenitis is commoner in children than at other ages, but it occurs frequently enough in young adults In an occasional instance of tuberculous lymphadenitis the lymph nodes break down and a sinus results Even in these cases recovery tends to occur spontaneously and often completely

In some instances, in those in a weakened condition, tuberculous lymphadenitis develops rather rapidly The development is slow in those who have good health.

In the beginning of tuberculous lymphadenitis the nodes are discrete but they tend to become matted together When these nodes remain discrete and are situated in the lateral triangles of the neck, there is a resemblance to the lymphoblastomas, especially of the Hodgkin type

Often a lesion is not suspected to be tuberculous until after it has been removed, cross section and microscopic study of the tissue then confirm the diagnosis.

Lymph nodes situated over the parotid gland are particularly likely to break down and to leave sluggish superficial ulcers. Once the skin is perforated, a chronic discharging sinus ensues.

Syphilitic and Mycotic Lymphadenitis. In former years it was taught that syphilis was a common cause of lymphadenitis of the neck. An enlargement of the lymph nodes in the posterior triangles of the neck, if the possibility of pediculosis capitis had been excluded, was considered to be almost pathognomonic of syphilis. It is now known, however, that there are many causes of subacute, chronic and indeterminate lymphadenopathies which include infections by bacteria, viruses or fungi, toxoplasmosis and diseases of unknown origin such as infectious mononucleosis

ULCERATIVE INFECTIONS OF THE NECK

Aside from ulcerating tuberculous lesions, the common pyogenic boil or furuncle, and fistulous tracts from congenital cysts, there are very few ulcerating lesions of the neck. Other than the lesions just named are those of the various fungi Blastomycotic ulcers on the neck usually are accompanied by ulcers elsewhere on the body, especially on the hands Sporotrichosis, likewise, which is common on the hands, may occur on the neck. Actinomycotic infection of the mouth or jaws may occasionally cause ulcerations of the neck Other uncommon causes of ulcers of the neck are Vincent's angina, leukemic tumors and abscess from the cervical vertebrae and dental infections

CAROTID SINUS SYNDROME

(*Vagal Syncope—Thomas Lewis, Nothnagel's Syndrome*)

The regulation of blood pressure is an autonomic proprioceptive reflex mechanism, which acts mainly by the intermediation of the pressoreceptor innervation of arterial and venous vascular areas (Weiss and Baker).

The bifurcation of the common carotid artery is richly supplied with sensory receptors which originate in the adventitia and leave the sinus as the sinus nerve to join the

n

can be responsible for attacks of unconsciousness and convulsions and that such attacks can be reproduced by slight trauma such as pressure over one carotid sinus The attacks are associated with cerebral anoxemia resulting either from cardiac asystole or from a primary reflex depression of the blood pressure. A hypersensitive state of the carotid sinus reflex may produce unconsciousness, convulsions or milder manifestations through one or more of three main reflex arcs The three motor pathways responsible for syncope involve the vagus nerve, the vasomotor depressor nerves or the central motor pathways. In a mixed form one or the other pathway may play the dominant role. In normal

subjects mechanical stimulation of the carotid sinus does not produce symptoms. The hyperactive carotid sinus reflex may be either unilateral, involving only one sinus, the activity of the other reflex remaining normal, or bilateral.

Three types of carotid sinus syndrome have been described. In the *vagal type* the symptoms, particularly the dizziness, fainting and weakness, result from cardiac asystole. The asystole is due either to sino-auricular or to auriculoventricular block, which in its turn produces acute cerebral anoxemia. In its pure form the afferent reflex travels over the vagus nerve to establish a heart block. The *depressor type* usually appears in association with one or the other two types The symptoms result from primary reflex vasodilatation and secondary depression of the blood pressure entirely unrelated to cardiac slowing or any form of cardiac arrhythmia. In the *cerebral type* the symptoms result apparently from impulses which travel directly to the brain. The attacks may be induced within as short a period as 5 seconds. Neither atropine nor epinephrine aborts or relieves the cerebral type of attack.

The loss of consciousness as a complaint may occur under diverse circumstances such as nervous upsets, claustrophobia, change in position, quick turning of the head, tight collar or blows on the neck. The reflex is more prevalent in men than in women. The frequency and degree of response increases as age advances. Coronary disease is the commonest condition in which the reflex occurs with the greatest frequency and the highest degrees of response.

The loss of consciousness may come on suddenly or gradually. There usually are pallor, sweating, severe weakness, nausea and sometimes dizziness with a sensation of falling The heart rate may drop, often to about 40, and the blood pressure falls rapidly The radial pulse is not palpable. The unconsciousness is of short duration; the patient is confused for a few minutes and weak for some time afterward. Sometimes following loss of consciousness a convulsive seizure ensues as in Adams-Stokes syndrome.

If a hypersensitive carotid sinus is suspected, an attack can be produced. Before inducing an attack, have the patient sit in a safe place to prevent injury in case he should fall. The attack is then precipitated by pressure or firmly stroking the area of the carotid sinus.

Vagovasal reflexes may bring about the same changes in some patients as those which follow swallowing with an inflamed or irritated pharynx or esophagus. The induced attacks are not dangerous but are unpleasant and, if frequent, cause nervous worry which probably favors more attacks. However, an occasional death has been recorded after artificial stimulation of the carotid sinus

These patients should have electrocardiographic studies to rule out a heart block before attempts are made to induce an attack or to stop an attack by the use of drugs. The attack should not be induced in any patient suspected of having an organic heart disease

PROTRUSION OF CERVICAL INTERVERTEBRAL DISKS

The sex distribution shows that affected males decidedly predominate. A history of trauma may occasionally be obtained. Before the appearance of symptoms of a medullary lesion, signs of cervical radiculopathy may be present.

The symptoms are extremely variable and resemble those of tumors and degenerative disease of the spinal cord Segmental symptoms, arising from root compression, may be present

The findings on physical examination are, like the symptoms, variable. In advanced protrusions of a disk the findings are those due to pressure on the spinal cord in this region Plain roentgenograms of the cervical portion of the spinal column may show extensive spondylosis deformans. Myelograms made by the injection of air into the cisterna magna reveal a subarachnoid space which is narrowed and distorted by an anterior protrusion, which reaches the spinal cord There

is no obstruction to the passage of the air into the thoracic subarachnoid space. In only a few cases will the protrusion be limited to one intervertebral disk.

TUMORS OF THE NECK

Tumors of the Carotid Bodies. These tumors are rare lesions which arise in the carotid bodies, which lie in the angle formed by the branching of the common carotid artery into its two branches. This angle is situated in the superior carotid triangle at a midpoint equidistant from the mastoid process, the angle of the jaw and the thyroid cartilage. Carotid tumors may develop, however, at considerable distances from this general situation. They may be bilateral and familial. These tumors grow very slowly, their development parallels that of the mixed tumors of the salivary glands. Pain transmitted to the region of the ear is occasionally present. In most of the rare instances of carotid tumor the growth is discovered when the neck is being palpated for lymph nodes. These tumors may become malignant; the chances are four in five, however, that they will remain benign.

Diagnosis is established by the presence of chromaffin cells at biopsy.

Ganglioneuromas. In Recklinghausen's disease (generalized neurofibromatosis) there are multiple tumors along the peripheral nerves all over the body. Some of these tumors may be situated in the neck. These multiple tumors, usually found in the deep midportion of the neck, grow very slowly (see Diseases of the Peripheral Nerves, Tumors, Chapter 6).

Diagnosis is suggested by the presence of Recklinghausen's disease but can be established definitely by biopsy.

Primary Cystadenomas. Cystic tumors of the neck comprise cystadenomas which arise in the lymph nodes, and cystic aberrant thyroid glands. The other cystic tumors which have been enumerated in the foregoing paragraphs are regarded as remnants of the gill clefts and cysts of the thyroglossal duct.

Lipomas and Myxomas. Lipomas of the neck are rare. They do occur in the lower and posterior regions. The myxoid tumors of the neck are more deeply seated generally than lipomas. However, good differentiation on palpation cannot be made between myxoid and lipomatous tumors.

Diagnosis is established by biopsy study.

Atheromatous Cysts. In common with dermoid cysts, atheromatous cysts or wens occur on the lateral surfaces of the neck, especially on the posterior portion. These tumors are definitely attached to the skin but their walls are distinct from the surrounding tissue.

Lymphoblastomas. *Lymphoblastomas of the Hodgkin type* involving the cervical lymph nodes are particularly difficult to differentiate clinically from tuberculosis. A common location of palpable lymph nodes in Hodgkin's disease is along and behind the midportion of the sternocleidomastoid muscle and in the supraclavicular fossa. These lymph nodes are often a conglomerate irregular mass, rather diffuse, tumor-like, and matted together. In Hodgkin's disease each lymph node maintains its independence, but the sense of touch may not interpret this individuality of existence of lymph nodes in a large mass which fills the whole region of the neck. If Hodgkin's disease is suspected clinically, often there are palpable nodes in the axillae and the inguinal regions because Hodgkin's disease or other diseases of the lymphoblastic group may arise first in these regions. The beginnings of Hodgkin's disease may be in the mediastinum or in the retroperitoneal lymph nodes, and the disease may be limited to these regions throughout its course, with very few nodes enlarged in the neck, axillary regions, or inguinal region. Hodgkin's disease may invade the skin.

Diagnosis of Hodgkin's disease is established by biopsy of a node.

The *lymphoblastomas of the sarcomatous type* are commoner in middle-aged men, whereas the lymphoblastomas of the Hodgkin type are commoner in young

men. Lymphosarcomas appear in the upper parts of the posterior triangles of the neck or just beneath the upper third of the sternocleidomastoid muscle. These tumors may begin in the anterior triangle of the neck and often in the supraclavicular fossa A common site of lymphosarcomas is in the mediastinum, where they are discovered by means of roentgenograms, usually after the tumors have invaded other tissues and some symptom is presented which requires roentgenologic examination of the thorax. Lymphosarcomas often invade the skin or the tissues surrounding them, and they grow rapidly.

Diagnosis is established by biopsy of an enlarged node.

Lympho-Epitheliomas (Endotheliomas) of the Lymph Nodes. A lympho-epithelioma usually appears at the angle of the jaw and often precedes or follows a pharyngeal tumor, a tumor of the cranial cavity, or a sinus. A characteristic feature of these tumors is that severe pain may attend the appearance of the initial enlarged node or even antedate its appearance.

Lympho-epitheliomas are fixed in position from the beginning These tumors are highly malignant, and the termination is an invasion of the neck and the mediastinum by direct extension

Diagnosis is established by biopsy of a lymph node.

Malignant or Secondary Tumors. Secondary tumors of the neck are metastatic tumors which occur within the lymph-drainage system from a primary malignant tumor and correspond in structure to the original tumor. It is not always possible to determine the site of the original tumor.

For the most part, however, the secondary malignant tumors of the neck are carcinomas that have originated on the lips, tongue, gums, floor of the mouth, nasopharynx, face or scalp In carcinoma of the stomach, testicles or kidneys there may be a small fixed lymph node—*Virchow's node* or sentinel or signal node—superior to the medial end of the left clavicle.

Melano-epitheliomas may occur on the lip or in the neck; they metastasize to all parts of the body. Metastatic tumors in the regions of the neck are prone to become secondarily infected from the oral cavity, irrespective of the site of origin

DISEASES OF THE PHARYNX

The mouth, the larynx, the esophagus, the two eustachian tubes and the two posterior nares open into the pharynx, which thus serves as the common tract for intake of air, food and drink.

Pharyngeal Openings The opening of the *mouth* into the pharynx sometimes is narrowed from cicatricial contractions resulting from ulcerative processes such as syphilis, and from burns due to swallowing of caustics. There rarely is obstruction downward, so that patients with such narrowing usually can swallow, but the cicatrices contract the opening upward, and the soft palate, its arches and the walls of the pharynx may be bound together in one cicatricial mass, preventing respiration through the nose

The opening between the *larynx* and the pharynx is easily accessible to those experienced in the procedure of examination If the tongue is drawn well forward, the tip of the epiglottis can be seen, and if a long straight tongue depressor is used, in many cases [illegible]

[illegible]

of the foreign body is in the larynx and part in the pharynx A foreign body can often be dislodged if the finger is thrust its full length into the mouth and throat and swept from side to side

The opening between the *esophagus* and the pharynx is in a line with the long axis of the pharynx. The opening of the larynx, on the contrary, is more on the anterior wall of the pharynx. It is for this reason that a tube introduced either through the mouth or through the nose passes into the esophagus and usually does not enter the larynx Excep-

tions to this rule occur more frequently in comatose patients in whom the tube passes more freely into the larynx.

The *eustachian tube* passes from the anterior portion of the tympanic cavity downward, forward and inward to the upper posterior portion of the pharynx The eustachian orifices, one on each side, are on a level with the floor of the nose. The upper border of the pharyngeal opening is approximately ½ inch (1 27 cm.) above the soft palate and about an equal distance below the basilar process. The lateral third of the eustachian tube, near the ear, is bony and the inner two thirds are cartilaginous. The isthmus of the tube is at the point of junction of the bony and cartilaginous portions and is the narrowest portion of the tube. The tube opens in swallowing and yawning and admits air to the tympanic cavity and mastoid cells. Interference with this process may cause the so-called aviation otitis with retraction of the ear drum during aeroplane trips. Catarrhal affections of the throat readily travel up the tube and set up an inflammation of the middle ear Swelling of the lining of the tube follows and air no longer passes to the ear.

The eustachian tubes are often involved in acute or chronic infections of the throat and middle ears The commonest symptoms related to eustachitis is popping and roaring noises in the ears These noises may be enhanced by or synchronous with the pulse beats.

The *posterior nares* open into the upper portion of the pharynx above the soft palate. This portion, the nasopharynx, differs from the oral and the laryngeal parts of the pharynx in that its cavity always remains patent.

Pharyngeal Diverticula. In pharyngeal diverticula the pouch opens into the pharynx by a transverse opening in the middle line about 1 inch (2 5 cm) in length The orifice varies in size in different cases and may be merely a slit. The pouch makes its passage between the pars obliqua and the pars fundiformis of the inferior constrictor immediately above the mouth of the esophagus There are two hypotheses as to the origin of these diverticula. the first, that they are due to embryologic defects; the second, that the cause is mechanical The theory that there is weakness in this region that is due to some sort of prenatal influence, concerned in the formation of either type of pouch, probably is correct

The symptom that is always constant in a pharyngeal pouch is the return of fragments of undigested food. This return is not immediately after the food has been taken, but many hours or even days afterward Solids are more troublesome to swallow than liquids, there is no dysphagia but the patient has to make two efforts before deglutition is accomplished. Abnormal secretion of saliva and difficulty in disposing of it may be the only sign in elderly persons. There is no vomiting or pain, but the patient may notice a gurgling noise in the throat, especially when lying down and at meals; this noise is followed by the bringing up of quantities of phlegm.

The diagnosis depends on the presence of fullness in a posterior triangle of the neck on which pressure produces a gurgling noise and the escape of gas into the mouth. The opening into, and the diverticulum itself, may be demonstrated by roentgenologic and endoscopic examinations.

Pharyngitis. The mucous membrane of the nasopharynx is ciliated columnar; that of the lower portion of the pharynx is squamous The mucous membrane contains racemose mucous glands and follicles or crypts surrounded by lymphoid tissue, and it is well supplied with blood vessels. The pharynx is frequently affected by inflammation or pharyngitis An abnormal general redness of or discrete eruptions [illegible] mucous [illegible] ta, ery- [illegible] ay also be seen. So also with petechiae, infarcts and extravasations of blood or bleeding surfaces.

When the lymph follicles are markedly involved, they can be seen studded over the posterior wall of the pharynx This constitutes follicular pharyngitis. Not infrequently some ulceration may be present, forming ulcerative pharyngitis. Should abscess formation occur around the pharynx, arising from an infection from the oral cavity, the pus occupies the retropharyngeal space between the buccopharyn-

geal fascia and prevertebral fascia. Its spread upward is limited by the skull; laterally, by the sheath of the carotid vessels; hence it passes downward behind the esophagus and may enter the posterior mediastinum.

The Pharyngeal Tonsil (Adenoids). The pharyngeal tonsil, composed mainly of lymphoid tissue, extends across the posterior wall and roof of the pharynx between the eustachian tubes.

Hypertrophy. The pharyngeal tonsil when enlarged hangs from the vault of the pharynx. It is a somewhat lobulated mass, and when large, in children, obstructs nasal respiration Under these conditions the disease known as adenoids is present. Mouth breathing results, and the child is likely to snore and make other queer respiratory sounds when sleeping These children may literally fight for breath at night.

A child who has reached 3 or more years of age and has marked adenoids presents a typical appearance The mouth is open, the lips are thick, the upper lip is elevated, the teeth project, the chin recedes, the alae nasi are atrophied and tense from want of use, and the nasal orifices are reduced to elongated slits. The philtrum is indistinct, and disuse of the muscles between the upper lip and the eyes gives the face a flat, smooth, characterless expression. Most such children have a more or less constant discharge of mucopus from the anterior nares, leading to excoriation and eczema of the upper lip The nose, however, in some cases may be dry. The adenoidal child often breathes noisily, owing to obstruction. The voice is often without resonance The most important secondary affection of adenoids is the effect on the organs of hearing According to some observers, almost one third of these children have some defect in hearing The facial expression may remain after the adenoids have been removed and persist into adult life.

Retropharyngeal Abscess. Retropharyngeal abscess may arise from any one of three causes: cervical caries, suppuration of lymphatic nodes, or extension of pus from the middle ear through the canal for the tensor tympani muscle Retropharyngeal abscesses occur external to the pharyngeal aponeurosis and bulge into the throat. Because of the looseness of this aponeurosis and its lack of firm attachments, these abscesses may not bulge forward as a distinct circumscribed swelling. They are more likely to gravitate downward and hang in a loose baglike manner opposite the base of the tongue They are too soft to be easily felt. They are more easily discovered by inspection In the search for the etiology of retropharyngeal abscess roentgenologic examination of the spinal column is made to detect the possible existence of spinal caries or Pott's disease, and the ear is examined for suppurative otitis media

Diseases of the Pharynx Due to Disturbances of Innervation or Psychic Control. *Anesthesia* of the pharynx is associated with hysteria and is indicative of some interference with the sensory functions of the glossopharyngeal and vagus nerves It is found in diphtheritic neuritis, hysteria and bulbar paralysis. Globus hystericus is a functional disorder of the ninth nerve

Spasm of the pharyngeal muscles on attempting to swallow is a functional affection of the motor portions of the same nerves It may be present in neurotic and hysterical individuals, in hydrophobia, true or false, in tetanus and in strychnine poisoning. It is probably an element in globus hystericus.

Paralysis of the pharynx, if bilateral, causes difficulty in swallowing, the food is not passed into the esophagus, and portions may enter the larynx. If the paralysis is unilateral, there is little if any difficulty in deglutition Pharyngeal paralysis indicates an involvement of the nuclei of the ninth and tenth cranial nerves or of the nerves in their course, as in bulbar paralysis, Landry's paralysis, and neuritis, or in basal lesions, as meningitis, tumor or aneurysm

Malignant Growths. Malignant disease is rare as a primary affection of the pharynx It is usually secondary to direct propagation in the last stage of cancer of

the larynx, the base of the tongue, a tonsil or the esophagus. Either carcinoma or sarcoma may occur; the former is the commoner.

In malignant disease in the region of the pharynx the patient at first complains of discomfort in the throat and interference with speaking, swallowing and nasal respiration Sharp pains develop early and extend to the neck, ears or angle of the jaw. Pain of burning character in the ear is a common symptom.

On examination there often is observed the presence of frothy mucus or saliva in one or both of the pyriform fossae. With the increase of the growth the voice may be hoarse, and respiration is observed to be seriously interfered with There are salivation, dysphagia, blood-stained sputum, foul breath and enlargement of the regional lymph nodes

The age of the patient, the one-sided affection, spontaneous pain and progress of the disease suggest the diagnosis It is established by biopsy study of tissue removed.

DISEASES OF THE LARYNX

The larynx is composed of the large epiglottis, the thyroid cartilage, the cricoid cartilage and three pairs of small cartilages

In the infant the larynx is situated opposite the second, third and fourth cervical vertebrae In the adult it has descended to the level of the fourth, fifth and sixth cervical vertebrae

The uppermost part of the epiglottis is below the dorsum of the tongue Extending forward from the epiglottis to the base and the sides of the tongue are three glosso-epiglottidean folds In the fossae formed by these folds, foreign bodies such as capsules, tablets and fish bones may become lodged Objects lodged here are easily seen by aid of the laryngoscopic mirror

The vocal cords lie immediately behind or just below the most prominent portion of the anterior edge of the thyroid cartilage, which commonly is called the Adam's apple

Examination of the Larynx Examinations of the larynx and the lingual tonsil to be of value require skill and considerably more knowledge of the procedures than can be gained by casual interest and an occasional attempt to make such an examination

The laryngologist may report the presence of swelling, ulceration or tumors on, above, or below the vocal cords In tuberculosis multiple ulcers may be seen Syphilitic or cancerous ulcers are usually described as single ulcers In the ordinary forms of laryngitis the vocal cords are said to be of a gray-pink or reddish color, and pinkish nodules may be present on the edges of the cords A failure of the cords to move properly, or paralysis, may be reported

Laryngeal Paralysis. Paralysis of the muscles of the larynx is rarely, if ever, due to cortical disease, but is caused by lesions affecting the nuclei or origin of the vagus in the medulla or the nerve itself at some part of its course Thus it may be implicated at its origin by the lesions of bulbar paralysis, syringomyelia, locomotor ataxia or multiple sclerosis, or an injury, tumor or disease of the base of the brain may involve the nerve near its superficial origin The causes of paralysis most frequently encountered are those which affect the vagus nerve or its laryngeal branches in the neck or the thorax, namely, in the neck, enlarged cervical lymph nodes, enlarged thyroid gland, tumors of the neck or the pharynx, and caries of the cervical vertebrae; in the thorax, aneurysm of the aorta, abscess, tumor, or enlarged lymph nodes in the mediastinum, esophageal cancer and, rarely, compression resulting from inflammation of the pericardium or pleura and pulmonary tuberculosis. The nerve and its branches may become inflamed (neuritis), or the laryngeal muscles themselves may undergo pathologic changes terminating in paralysis as an effect of the toxins of a number of the acute specific infections, notably diphtheria; or chronic poisoning, especially from lead and alcohol.

Total bilateral paralysis is most commonly indicative of aneurysm of the thoracic aorta, cancer of the esophagus, great enlargement of the thyroid, or mediastinal tumor.

Abductor paralysis is commonly unilateral and is the most frequent variety of laryngeal palsy.

Adductor paralysis, either bilateral or unilateral, is as a rule of functional origin.

Paralysis of the *interarytenoid muscle* (adductor) is most likely to be a symptom of hysteria.

Paralysis of the *internal thyro-arytenoid muscles* (adductors) is a not uncommon result of overuse of the voice and laryngeal inflammation.

The Voice (The Faculty of Speech). A loss of voice or whispering voice (aphonia) and coarse or harsh quality of the voice (hoarseness or dysphonia) are both due to some interference with the function of the vocal cords. Abolishment of action of the cords may be due to local and inflammatory disease of the larynx or to disease of or pressure on the recurrent laryngeal nerve Aphonia may come suddenly or be preceded by hoarseness, or the latter alone may be present.

In the majority of cases aphonia and hoarseness are due to some form of laryngitis, such as the acute or chronic catarrhal variety associated with acute infections of the upper part of the respiratory tract, syphilis or tuberculosis Edema of the glottis and retropharyngeal abscess are occasional causes Excessive use of the voice or excessive cigarette smoking may induce congestion of the cords, and cause hoarseness or aphonia Tumor of the larynx, impacted foreign bodies and cicatricial stenosis of the larynx may be found responsible.

Disorders of Speech from Involvement of the Laryngeal Nerves. The larynx receives its nerve supply from the superior and inferior laryngeal branches of the vagus nerve. Interference with their functions gives rise to anesthesia of the larynx or paralysis of the laryngeal muscles, manifested by aphonia, hoarseness and, if the abductors are affected, dyspnea.

If there is a deep, hoarse voice and a brassy cough, with a tendency for particles of food to enter the larynx, there is probably interference with the superior laryngeal nerve, giving rise to anesthesia of the upper portion of the larynx and paralysis of the cricothyroid muscles This interference is often due to bulbar paralysis, a peripheral neuritis, or the pressure of a tumor such as a goiter or carotid aneurysm.

If there is aphonia without cough or dyspnea, it may be due to paralysis of all the laryngeal muscles caused by bulbar paralysis, tumors of the medulla, diphtheria, or pressure on both recurrent nerves; or to complete paralysis of the adductors, which is usually of functional origin, but may occur from overuse of the voice or laryngitis.

Hoarseness, with easy fatigue on slight use of the voice, is indicative of unilateral abductor paralysis, of which the commonest cause is a mediastinal tumor or an aneurysm pressing on one recurrent nerve If right-sided, it may be due to a much thickened pleura, cancer of the upper part of the esophagus or mediastinal tumor.

A modified but understandable voice and phonation may be maintained in the presence of a dangerous laryngeal paralysis resulting from locomotor ataxia, bulbar palsy or pressure from a tumor or aneurysm

A rattling, rough voice, the so-called ventricular voice, is due to the occasional vicarious vibration of the false vocal cords or ventricular bands in cases in which the true cords are paralyzed or destroyed by ulceration. Other abnormalities of the voice consist in a double or triple splitting of the sounds In the first variety the two sounds, although simultaneous, differ in pitch (diplophonia, diphthongia); this phenomenon is due to a small tumor on the edge of one vocal cord or to unilateral paralysis of the cords The triple voice is very uncommonly observed and is caused by a pedunculated tumor which has its attachment below the vocal cords. During

the early portion of phonatory expiration the growth rises, the voice is clear; during the middle part it lies between the cords, the voice is of normal tone but of decreased volume; and during the latter part the tumor has been protruded to a point above the glottis and the voice is clear.

The peculiar quality of voice which goes by the name of nasal voice is sometimes a matter of habit and lack of training of the voice. It is of service to recognize two varieties of the nasal voice. The first, the *open nasal*, is caused by nonclosure of the nasopharyngeal opening by the soft palate and may be imitated by speaking without opening the mouth, the second, the *closed or stopped nasal*, is due to nasal stenosis, and resembles the tone imparted to the voice by speaking while the nose is pinched between the thumb and forefinger.

The open nasal tone is indicative of a congenital cleft of the palate, of paralysis of the soft palate, or destruction of the soft palate. The closed nasal voice is often present in coryza, hypertrophic rhinitis, nasal polyp or postnasal adenoids.

Dumbness or *mutism*, inability or unwillingness to speak, may be present in hysteria, idiocy, melancholia and dementia Feigned inability to speak is sometimes resorted to by malingerers. A real inability to speak may be due to cerebral fatigue which succeeds a severe and exhausting illness, particularly severe fevers. Mutism exists in those who are congenitally deaf, or in children who become totally deaf before the power of speech is permanently acquired.

Anarthria, indistinct or imperfect speech, the impairment varying in extent, may be an evidence of paralysis of the tongue, soft palate and facial muscles. Glossitis, parotitis and the absence of teeth may be responsible for a mumbling manner of talking

A *slow, interrupted* manner of speech, the words being slurred over, somewhat as if the patient were intoxicated, with tremulousness of the tongue and lips, is observed in general paresis and myxedema

A *piping, querulous* voice, with manifest hesitation in beginning a sentence, the words then being rapidly spoken, is characteristic of paralysis agitans.

Scanning speech, in which the words are spoken slowly, each syllable accented as if reading verse, is an important symptom of multiple sclerosis but is also found in Friedreich's (hereditary) ataxia.

These disturbances of the voice may be of such nature that their final diagnosis and differentiation require a consideration of the faculty of language

The Faculty of Language. Normal Speech Mechanism. The normal exercise of the faculty of language depends on the existence and integrity of certain cerebral centers (1) psychic centers of intelligent perception, (2) sensory receptive centers, (3) emissive or motor centers and (4) the association tracts Finally, there are the basal ganglia for the special senses and the nuclei in the medulla and spinal cord actuating the muscles employed in articulate speech, which constitute respectively the sensory and motor peripheral apparatus

Apraxia. If an individual has varying degrees of defects in the power of recognizing or understanding the nature and uses of objects or, possibly, the identity of persons, the condition is termed apraxia The varieties of apraxia correspond in number and character to the varieties of sensations. mind blindness, mind deafness, mind anosmia, mind ageusia and mind atactilia.

Apraxia is closely allied to, and is often found in connection with, the various forms of aphasia, that is, an inability to produce or understand spoken or written speech (see The Nervous System and Locomotion, Chapter 6).

Aphasia and Its Varieties. The term aphasia embraces a variety of defects in the use or in the comprehension of language, either spoken or written. In order to understand and interpret this symptom and its several forms a conception of the *normal* manner and mechanism of the faculty of language is desirable. The subject is complex, and many exceptional and often unexplainable cases occur. As far as

possible the statements made here are those the truth of which is considered as probable.

MOTOR OR ATAXIC APHASIA. This variety embraces as its most important division *aphemia*, the loss of power to utter words, although the patient knows what he desires to say, because he cannot revive the motor memories for articulating them. Occasionally these patients may be able to sing even though they fail in attempts to talk. This sort of aphasia is common to most aging persons—those 50 years or more of age—in a mild form *Agraphia* is inability to write words for lack of power to recall the motor memories of the muscular actions involved in writing.

SENSORY APHASIA. The principal varieties of sensory aphasia are the auditory and visual. *Auditory aphasia* or word deafness is, as its name indicates, an inability to recognize words when spoken The patient hears, but does not understand, as if listening to a foreign language *Visual aphasia* or *alexia* is a condition in which the patient sees, but does not recognize or understand written or printed words. *Memory aphasia* consists of inability to recall the sound of a word or phrase. Once the sound is recalled, the word or phrase can be spoken. This is a form of sensory aphasia incident to aging

EXAMINATION FOR APRAXIA AND APHASIA. To determine the presence of *word deafness* (auditory aphasia), the examiner must elicit the information indicated by the following questions.

1. Can sounds be heard by the patient? Ability or lack of ability to hear determines the presence or absence of ordinary deafness
2. Can spoken words be heard by the patient? If so, then
3. Can the spoken words be understood? This may be ascertained by having the patient put out the tongue, open and close the hand A failure to comply indicates inability to attach any meaning to the words, and word deafness is present, which is the principal symptom of auditory aphasia

To determine the presence of *word blindness* (alexia, visual aphasia):

4 Can the patient see objects?
5. Can written words be read?
6 Can written or printed words be understood? This may be ascertained by writing out a question, or a direction, for instance, "Close your eyes." A failure to comply indicates word blindness, which is the principal symptom of visual aphasia

To determine the presence of *motor aphasia* (aphemia)·

7. Can the patient speak voluntarily?
8. Can words be repeated?
9 Can the patient read aloud? If unable to do these things, motor aphasia or aphemia is present

To determine the presence of *agraphia*

10. Can the patient write?
11. Can dictation be written?
12. Can a sentence or words be copied? If he is unable to do these things, agraphia, a symptom which may be found in all forms of aphasia, is present. If the patient is unable to write voluntarily because of inability to remember words or their appearance, but can write to dictation, the disability is sensory agraphia. If it be impossible to write either voluntarily or to dictation, a motor agraphia is present

To determine the presence of *mind blindness*

13. Are ordinary objects recognized and their uses known? Put before the patient two or three familiar objects and question him about one of them. If the proper article is not picked up, the subject has mind blindness, provided that inability to understand the request is owing to word deafness

To determine the presence of *mind deafness*.

14 Does the patient recognize ordinary sounds, that is, does the ring of a bell, the ticking of a watch, awaken a recognition of its import? If not, the patient has mind deafness.

There are variations in the degree of all the speech defects There may be only a

the early portion of phonatory expiration the growth rises, the voice is clear; during *the middle part it lies between the cords, the voice is of normal tone but of decreased* volume; and during the latter part the tumor has been protruded to a point above the glottis and the voice is clear.

The peculiar quality of voice which goes by the name of nasal voice is some*times a matter of habit and lack of training of the voice. It is of service to recognize* two varieties of the nasal voice. The first, the *open nasal,* is caused by nonclosure of the nasopharyngeal opening by the soft palate and may be imitated by speaking without opening the mouth, the second, the *closed* or *stopped nasal,* is due to nasal stenosis, and resembles the tone imparted to the voice by speaking while the nose is pinched between the thumb and forefinger.

The open nasal tone is indicative of a congenital cleft of the palate, of paralysis of the soft palate, or destruction of the soft palate The closed nasal voice is often present in coryza, hypertrophic rhinitis, nasal polyp or postnasal adenoids.

Dumbness or *mutism,* inability or unwillingness to speak, may be present in hysteria, idiocy, melancholia and dementia Feigned inability to speak is sometimes resorted to by malingerers. A real inability to speak may be due to cerebral fatigue which succeeds a severe and exhausting illness, particularly severe fevers. Mutism exists in those who are congenitally deaf, or in children who become totally deaf before the power of speech is permanently acquired.

Anarthria, indistinct or imperfect speech, the impairment varying in extent, may be an evidence of paralysis of the tongue, soft palate and facial muscles Glossitis, parotitis and the absence of teeth may be responsible for a mumbling manner of talking.

A *slow, interrupted manner of* speech, the words being slurred over, *somewhat* as if the patient were intoxicated, with tremulousness of the tongue and lips, is observed in general paresis and myxedema.

A *piping, querulous* voice, with manifest hesitation in beginning a sentence, the words then being rapidly spoken, is characteristic of *paralysis agitans*

Scanning speech, in which the words are spoken slowly, each syllable accented as if reading verse, is an important symptom of multiple sclerosis but is also found in Friedreich's (hereditary) ataxia.

These disturbances of the voice may be of such nature that their *final diagnosis* and differentiation require a consideration of the faculty of language.

The Faculty of Language. ***Normal Speech Mechanism.*** The normal exercise of the faculty of language depends on the existence and integrity of certain cerebral centers. (1) psychic centers of intelligent perception, (2) sensory *receptive centers,* (3) emissive or motor centers and (4) the association tracts. Finally, there are the basal ganglia for the special senses and the nuclei in the medulla and spinal cord actuating the muscles employed in articulate speech, which constitute respectively the sensory and motor peripheral apparatus

Apraxia. If an individual has varying degrees of defects in the power of recognizing or understanding the nature and uses of objects or, possibly, the identity of persons, the condition is termed apraxia. The varieties of apraxia correspond in number and character to the varieties of sensations. mind blindness, *mind deafness,* mind anosmia, mind ageusia and mind atactilia

Apraxia is closely allied to, and is often found in connection with, the various forms of aphasia, that is, an inability to produce or understand spoken or written speech (see [illegible] Chapter 6).

Aphasia [illegible] variety of defects in the use of [illegible] written. In order to understand and interpret this symptom and its several forms a conception of the normal manner and mechanism of the *faculty of language is desirable.* The subject is complex, and many exceptional and often unexplainable cases occur. As far as

tracheitis, acute obstructive laryngotracheobronchitis, and an unclassified noninfectious croup due to allergy, foreign body and chemicals or other irritative agents). The presence or absence of supraglottic edema and the position and motion of the vocal cords before and after suctioning of the subglottic area and trachea have furnished a dependable guide to the choice of therapy

Here the interest is in spasmodic croup

Spasmodic croup is a form of laryngeal stridor of unknown etiology, characterized by sudden onset and unaccompanied by fever It affects children, more commonly boys than girls, between the fourth month and the end of the second year of life. The attacks may continue until the child is approximately 10 years of age.

The disease affects feeble, undernourished children who often have nasopharyngeal adenoids, enlarged faucial tonsils, enlarged bronchial lymph nodes and disorders of the upper air passages

The child as a rule goes to sleep as usual He suddenly is awakened from a sound sleep struggling for breath. The forced effort at inspiration produces a croupy, crowing stridor. In the effort to fill the lungs the child sits up in bed, tosses his hands about, holding to the nearest support or clutching his throat All the accessory muscles of respiration are thrown into action. The mouth is open, the nostrils are dilated and the chest is heaving, but as all these efforts fail to fill the lungs, the diminished pressure causes retraction of the lower ribs and the manubrium sterni. The expression is one of terror as the patient becomes cyanotic. The head is thrown back and the child is soon covered with sweat In severe attacks respiration may cease for a few seconds In such cases there are carpopedal contractions, convulsions and even involuntary passage of urine and feces The attacks are usually of short duration, often less than a minute, and rarely do they exceed 2 minutes. The attack is ended by one long, deep, relieving inspiration Relief from the attack is followed by a croupy cough. Further attacks may take place during the same night, and they often recur from night to night for some time After the attack the child falls asleep and the next morning his health is as usual.

The diagnosis of this condition is not difficult if it is remembered that the paroxysms characteristically begin with sudden onset and without fever and hoarseness and end as abruptly as they begin

Syphilis. Ulcers of syphilitic origin may involve almost any portion of the larynx but they usually are anterior and involve the epiglottis. These ulcers often are associated with syphilitic manifestations in the mouth which are ulcers that are most marked posteriorly, blanching of the mucous membrane of the mouth and the presence of a white frothy mucus The serologic reactions for syphilis are positive

Stenosis. Acute laryngeal stenosis is met with in wounds, injuries, foreign bodies, acute laryngitis, septic inflammation, diphtheria, membranous laryngitis, the exanthems and syphilis. It has been known to occur rather suddenly in tuberculosis of the larynx

The chief symptoms of laryngeal stenosis are dyspnea, stridor, and alteration or extinction of the voice All of these symptoms are intensified on exertion. The patient prefers to sit up in bed, for breathing seems easier in this posture It is remarkable how hard a patient may be striving for air in this condition and yet be free from marked cyanosis

The diagnosis is established by laryngoscopic examination.

Laryngeal Symptoms of Nervous Origin. The laryngeal symptoms in mediastinal tumor are due to irritation of, or pressure on, the vagus nerve or its recurrent laryngeal branches There are cough, attacks of dyspnea and alterations in the voice. In the irritative stages the cough is paroxysmal, hoarse, imperfect and brassy. When one or both recurrent branches are completely paralyzed, the cough loses its sharp, ringing character and becomes hollow and blowing.

partial loss of any one of the normal powers of expression, depending mainly on the extent of the productive lesion.

DISEASES WHICH CAUSE APHASIA. In the majority an aphasia is one of the symptoms of organic focal cerebral disease, occurring in the left hemisphere in right-handed persons, and vice versa. The localization and appraisal of aphasia is the work of the neurologist. Aphasia may occur as the result of a cerebral hemorrhage, thrombosis, embolism, abscess or tumor.

In rare instances aphasia occurs in hysteria and neurasthenia and epilepsy. It is an occasional symptom in migraine, and may be present during convalescence from severe and exhausting fevers

Infections of the Larynx. ***Acute Laryngitis.*** Acute laryngitis is an acute catarrhal inflammation of the mucous membranes of the larynx manifested by hoarseness or aphonia and occasionally by cough The acute inflammation may primarily attack the larynx, whence it spreads downward to the trachea and bronchi or upward to the nose. Frequently the laryngitis is but an extension downward of an acute catarrh of the nose or the pharynx. Or, rarely, an acute inflammation first develops in the bronchi and spreads upward to the larynx. The attack often is precipitated by excessive and, more particularly, improper use of the voice It may follow on the vomiting and retching of an alcoholic debauch, an attack of seasickness or a passionate attack of crying or sobbing

In the early stages of acute laryngitis the visible changes in the larynx may be very slight, but as the hoarseness increases, the signs of inflammation increase proportionately

When uncomplicated, an acute laryngitis is without danger and subsides within from 3 to 10 days

Chronic Laryngitis. Chronic laryngitis is a catarrhal inflammation of the mucous membranes of the larynx, characterized by an impairment and alteration of the voice Disorders of the nasal and the postnasal cavities and, to a less extent, of the pharynx and mouth are the most potent factors in originating chronic laryngitis. The alteration of the voice is at first an intermittent huskiness, but when the symptom is well established, the hoarseness is persistent; it is more marked after a rest or on arising in the morning than at other times and tends to disappear after a little use of the voice The tone of the voice is lowered; aphonia is seldom complete, except after prolonged or extreme forcing of the damaged organ A sense of fatigue and soreness of the throat may be present. There is frequent clearing of the throat by hemming and hawking

On physical examination the mucous membrane is congested. The vocal cords may be only slightly affected but often appear dull and gray.

The diagnosis usually is not difficult for the examiner who is trained in inspecting the larynx. Because tuberculosis of the lung may be accompanied by a chronic and inveterate laryngitis. care should be taken to exclude the possibility of this disease

Nodular laryngitis is a form of chronic laryngitis generally caused by faulty use of the voice and characterized by local thickening of the vocal cords The symptoms are those of chronic laryngitis. The diagnosis is madé by one who is accustomed to inspect the vocal cords and larynx.

The laryngologist may describe other forms of laryngitis such as (1) hypertrophic laryngitis and (2) chronic atrophic laryngitis

Laryngismus Stridulus or Spasmodic Croup. Gilbert and associates have called attention to the multiplicity of names for croup and offer the following classifications. (1) diphtheritic croup with three subgroups (diphtheritic obstructive laryngitis, laryngotracheitis and laryngotracheobronchitis) and (2) nondiphtheritic croup with five subgroups (acute catarrhal laryngotracheitis, supraglottic edematous obstructive laryngitis, subglottic obstructive exudative and edematous laryngitis and

CARCINOMA OF THE VOCAL CORDS Four of each five laryngeal cancers arise on the vocal cords. Cancer of the vocal cords is almost always either squamous cell carcinoma or papillary carcinoma The low inherent malignancy of these neoplasms in the presence of poor lymphatic drainage of the true cords renders carcinoma arising on the cords likely to remain localized for a considerable period of months, occasionally longer.

The cardinal and only early symptom of carcinoma of the vocal cords is hoarseness Hoarseness in middle-aged or aging men which persists for more than 2 weeks requires inspection of the larynx.

A general physical examination does not reveal any significant findings so long as the laryngeal tumor is limited to the structure Early evidence of extension is recorded by the otolaryngologist as immobility. Only in extensive spread will there be any palpatory evidence present

All lesions of the larynx are examined for evidence of syphilis.

Examination of the thorax may aid in differential diagnosis in regard to tuberculosis and syphilis Roentgenograms of the larynx may be helpful in indicating the site of origin, position, and extent of laryngeal tumors

Biopsy is necessary to establish the identity of any proliferative or ulcerative lesion of the cords. Benign papillomas may cause confusion, even on microscopic examination. Repeated biopsies are occasionally necessary There is no evidence to indicate that carefully performed biopsy on the vocal cords increases the danger of spread of cancer.

Surgical treatment is the preferred procedure when the lesion is limited; otherwise radium may be used

Leukoplakia Laryngis. Leukoplakia of the larynx is characterized by white thickenings of the upper surface of either or both of the vocal cords that appear much the same as the patches of leukoplakia of the tongue Leukoplakia laryngis can be diagnosed only by a physician of a great deal of experience in examinations of the larynx.

DISEASES OF THE TRACHEA

Acute Tracheitis. Acute tracheitis is usually a part of the common cold, although in some instances an acute infection seems to be limited to the trachea

The symptoms of acute tracheitis vary in intensity, and the duration is comparable to that of acute bronchitis The symptoms consist of hoarseness, cough and perhaps fever and ineptitude The diagnosis is by inference if the patient promptly recovers the voice and if the cough and the fever cease

Chronic Tracheitis. A chronic tracheitis, often of severe grade, frequently arises from a long-continued inhalation of irritating fumes or dusts or from excessive tobacco smoking Chronic infection of the paranasal sinuses, mouth, nose and throat, when the discharges are aspirated into the trachea, frequently results in chronic tracheitis and bronchitis

An endoscopic examination may be necessary as diagnostic proof if the rest of the respiratory system is normal

Tracheal Stenosis. Irritating gases, corrosive fumes, and acute and intense infections may cause stenosis of the trachea, which may reach such a degree as to result in severe dyspnea and extreme cyanosis. This often occurs during the course of an ordinary bad cold

Tumorous growths inside or pressure from outside the trachea may cause a chronic, slowly progressive stenosis. Trauma and slowly progressive infections such as that of syphilis also may produce stenosis

Rupture of the trachea, usually due to the trauma of instrumentation, as a rule is fatal When tracheal rupture occurs from trauma of other origin, the condition

In tabes dorsalis there may be laryngeal anesthesia, paresthesia or hyperesthesia. The symptoms are described respectively as tickling, irritation, and tightness or a sensation of choking. The voice becomes thick and jerky, owing to ataxic movements of the cord. Laryngeal crisis often occurs in the early stage and may precede other signs of the disease by several years The laryngeal crisis and spasmodic attacks vary much in intensity and frequency; they seldom cause death by asphyxia

Other diseases of the nervous system which may affect the larynx are disseminated sclerosis, bulbar palsy, dystrophia myotonica (myotonia atrophica), myasthenia gravis and syringomyelia

The diagnosis is suspected when there are attacks of dyspnea, alterations in the voice, and cough during the course of the aforementioned diseases

Laryngeal Vertigo. Laryngeal vertigo (laryngeal syncope, laryngeal epilepsy) occurs in middle-aged neurotic men who are suffering from laryngitis, bronchitis, bronchial asthma or pulmonary tuberculosis The attack begins with laryngeal tickling or irritation, followed by a short cough, spasm of the larynx, dyspnea, transitory syncope and slight convulsive movements Such attacks may recur every day or at intervals of a month or more

Laryngoscopic examination is impossible during the attack and the findings are negative in the interim The diagnosis is made from the history and the presence of an obvious psychoneurosis Serious deterioration of health may follow the onset of laryngeal vertigo.

Tumors. Benign Tumors. Benign tumors of the larynx are comparatively rare In this group the *papilloma* is the commonest It occurs earlier than any other type of benign tumor, and may be congenital Nearly all laryngeal growths met with in infants and in children up to the age of 10 years are of this character.

CYSTOMA Pathologically cysts of the larynx are due to retention from obstruction in the duct of a muciparous gland Their commonest situation is on the anterior surface of the epiglottis

OTHER BENIGN TUMORS Lipoma is a rare tumor of the larynx, as are angioma, adenoma, myxoma, lymphoma, neurofibroma and tumor of the thyroid gland. The last-named tumor, which may arise from abnormal distribution of thyroid tissue, is extremely rare and of relatively little importance.

LARYNGEAL POUCH This pouch is conveniently referred to here because it clinically resembles a benign tumor, although its pathologic origin is uncertain. Laryngeal pouch, the so-called prolapse of the ventricle of Morgagni, is a membranous sac between the superior vocal cord and the thyroid cartilage On examination a smooth, pink, fleshy growth with a broad base is seen issuing from the ventricle of Morgagni and resting on the vocal cords

Malignant Tumors. Both carcinomas and sarcomas occur in the larynx In appearance and symptoms carcinoma and sarcoma of the larynx are so much alike that biopsy must be performed to establish the diagnosis

Carcinoma of the larynx may occur without involvement of the vocal cords, or these structures may be primarily affected

Lesions of the larynx which do not involve the vocal cords have their origin in the epiglottis, the false cords, the ventricular cavity, or the subglottic area. These lesions cause virtually no early symptoms, and are usually not discovered until there is pain, extensive infiltration of cartilage and muscle, or metastasis to the regional lymph nodes With the occasional exception of lesions localized on the tip of the epiglottis, pain is seldom a complaint until the disease is well advanced and then pain often is severe, extending to the ear and the side of the head and being much increased by swallowing. Respiratory obstruction is marked when these intrinsic lesions advance. There may be pharyngeal symptoms and interference with deglutition. These lesions may not be amenable to resection but many are radiosensitive.

During the active secondary stage of syphilis, changes in the trachea and bronchi may occur, resulting in symptoms of an acute tracheitis or bronchitis. Mucous patches develop, and in the tertiary stage gumma is sometimes seen in the trachea and bronchi. Cough is usually the first symptom of this condition The gumma may be absorbed, so that the cough does not become productive. If ulceration occurs, however, considerable mucopurulent sputum is produced From such ulcers there often is blood-streaked sputum or even frank hemorrhage. These ulcers occasionally extend through the wall of the trachea or a bronchus and invade the adjacent structures, such as the mediastinum, the esophagus and even the pulmonary artery. Stenosis of various degrees results in difficulty in respiration, even to the point of terminating fatally. In such cases the physical findings, including results of roentgenologic examination do not differ from those caused by stenosis from other causes.

Diagnosis is sometimes assisted by the detection of syphilitic disease, or its scars, in the nose, pharynx, or larynx, but in many cases these aids are not forthcoming, and then the cause of the stenosis is arrived at by inspection, or by endoscopy.

The prognosis will depend on the degree and the depth of the stenosis. In cases in which the contraction is low down, or cannot be relieved, or extends into the bronchi, the outlook is very grave

Syphilis of the Lungs. O'Leary was able to prove the diagnosis of syphilis of the lungs in only 6 instances over a period of 20 years

Syphilis of the lungs is so rare that the symptoms are unknown

The diagnosis is made by exclusion There are nodular infiltrated lesions in the upper pulmonary fields, positive results of serologic tests of the blood and negative results from other diagnostic laboratory procedures A therapeutic test for syphilis is said to confirm a presumptive diagnosis when the symptoms disappear, roentgenologic examination shows that the lesions in the lungs have disappeared, and the patient gains weight and comments on how well he feels The serologic reactions of the blood do not show any significant change until many years later.

Tumors. ***Benign Tumors.*** The benign growths of the trachea are papilloma, fibroma, lipoma, adenoma, hemangioma and lymphoma, lymphadenoma, mixed parotid tumors, osteoma, enchondroma, and aberrant thyroid tissue tumors Papillomas and fibromas are, as in the larynx, the commonest. Papillomas of the trachea, the most frequent growths of all, are generally extensions from the larynx, and hence occur in young children Fibromas come next in frequency.

If the growth is in the trachea, symptoms may be noticed only when there is considerable stenosis The patient usually first complains of dyspnea. This may occur suddenly and fatally The voice is usually enfeebled, though not lost. Hoarseness will depend on the degree to which the vocal cords are involved by catarrh Simple neoplasms of the bronchi generally attract attention in the first place by causing hemoptysis Dyspnea is not severe, but obstruction to the escape of secretions from the lung produces cough and expectoration of infected sputum, sometimes of fetid character

The effects are mechanical, owing to lack of aeration and drainage of the lung beyond the point of obstruction The neoplasm in such case may occlude the trachea. It may, however, if pedunculated, be pulled down during inspiration and cause obstructive emphysema by its reversed check-valve action

If there are manifestations of obstruction of the trachea, information may be gained by roentgenography

Amyloid Tumors of the Larynx and Trachea. The larynx and the trachea are common sites of localized deposition of amyloid. Amyloid tumors of the larynx, trachea or bronchi may occur in association with amyloid degeneration elsewhere in the body or as isolated deposits The isolated deposits, according to New, may be divided into (1) diffuse subepithelial infiltrations, (2) tumor-forming amyloid deposits, and (3) amyloid degeneration in a pre-existing tumor

usually is not suspected because of the other serious symptoms resulting from the trauma. Spontaneous rupture rarely occurs Tracheo-esophageal fistula is fortunately rare. These fistulas cause severe respiratory distress and dysphagia

In summary, all of these conditions, namely, acute tracheitis, chronic tracheitis, tracheal obstruction and stenosis, and tracheo-esophageal fistula, may be diagnosed clinically. However, roentgenoscopic and bronchoscopic confirmations are obtained when warranted by the conditions

Acute Laryngotracheobronchitis. Acute laryngotracheobronchitis occurs in children and in the aged *Streptococcus hemolyticus* and *Hemophilus influenzae* are causative organisms There is a sudden onset of cough, dyspnea and cyanosis. A tenacious and thick, later purulent, exudate is coughed up. The tenacious secretions may obstruct bronchial ramifications and thus produce atelectasis Mediastinal emphysema and spontaneous pneumothorax may result from overdistention of the alveoli. On examination of the chest there are noisy coarse rales but no changes on percussion or in the breath sounds.

The diagnosis is established by the history and the physical findings. Roentgenoscopic examination in either children or the aged differentiates this condition from bronchopneumonia

Ulcerative Tracheobronchitis. The tracheobronchial ulcerations may result from recurring attacks of atypical pneumonia, bronchiectasis, abscesses, tuberculosis, sarcoidosis and fungous infections The characteristic symptom is persistent cough with considerable blood-streaked sputum which occasionally contains gross blood Fever and loss of weight or failure to gain weight are often present Examination by physical means usually gives negative results

The diagnosis is established by seeing the ulcerations with the bronchoscope The etiologic diagnosis may be made from materials obtained for pathologic and bacteriologic studies The prognosis depends on the etiology.

Syphilis of the Trachea, Bronchi and Lungs. Congenital Syphilis. This disease may occur in the larynx, trachea, bronchi and lungs of the fetus and the newborn child Since the tracheal lesions may be the commoner, and all of these structures may be synchronously affected, they are all considered at this time.

Acquired Syphilis. Syphilis attacks any part of the larynx, the vocal cords, the trachea and the bronchi Mucous patches may appear in the larynx Tertiary laryngeal lesions are rare However, they have been reported to result in partial or complete stenosis of the larynx Deep ulcers sometimes occur, and the disease may extend so as to result in external fistulas

SYMPTOMS. Often there are hoarseness and difficult breathing when edema becomes severe Loss of voice may occur in severe infections Laryngeal scarring sometimes results in permanent difficulty in breathing

DIAGNOSIS When the disease is diagnosed by the history, positive serologic reactions, the appearance of the lesions, and biopsy, and if the patient is treated promptly before much destruction has occurred, the prognosis is good There may remain unfortunate conditions such as stenosis of the larynx

Syphilis of the Trachea and Bronchi. Erythema, mucous patches, gummas, perichondritis and subsequent cicatricial stenoses occur in the trachea and bronchi Diffuse gummatous infiltrations are commoner than the localized gumma. They are most frequent at the lower end of the trachea, near its bifurcation; next in frequency come extensions from the larynx, and, lastly, those situated midway between these points. Syphilitic ulceration and stenosis may extend into the main bronchi Complications occur from perforation of the esophagus, aorta, pulmonary artery or vena cava, but the commonest sequela is stenosis.

Syphilitic ulcerations of the trachea are considered to be of rare occurrence Syphilitic stenosis of the main bronchi, without a similar condition in the trachea, is

In the larynx amyloid deposition is almost entirely associated with a generalized amyloidosis. Though laryngeal symptoms occur, these usually can be detected and identified as a part of the generalized lardaceous process. The lesion occurs more frequently in men than in women in about the ratio of 3 to 1.

The majority of patients are between the ages of 50 and 70 years at the time the diagnosis of amyloid tumor is made In cases reported in the literature, the youngest patient was 19 years of age and the oldest patient was 80 years old.

SYMPTOMS. When symptoms are present, they are caused by the physical presence, size and location of the tumor. There are hoarseness and dyspnea. Willmann reported a case in which the diagnosis was made 6 weeks after the onset of symptoms Thompson described a case in which the chief symptom of hoarseness, in a woman 32 years old, had been present at least 25 years before the diagnosis of deposition of amyloid was made The usual duration of symptoms before diagnosis has been between 1 year and 2 years.

EXAMINATION The gross appearance of the amyloid tumor has been said to be a waxy, translucent, yellow or yellow-gray swelling without ulceration of the overlying mucosa The lesion has been reported to have either a smooth or a nodular outline, and to be either diffuse or well localized and red The tumor is hard on palpation

DIAGNOSIS The diagnosis of an amyloid tumor is determined by microscopic examination of sections of tissue from the lesion. The extent of the lesion may be determined visually by laryngeal examination, roentgenologic examination, tracheoscopy or bronchoscopy Evaluation of the extent of a recurrent lesion or a lesion of which the diagnosis has been established may be simplified by staining of the amyloid by the intravenous injection of Congo red

Malignant Tumors. Malignant disease of the trachea is not common. Most of the malignant growths present in the trachea are but extensions from the larynx, esophagus, or mediastinum. They are much commoner toward the upper end of the trachea than toward the lower end, and more often affect the posterior wall than the anterior wall

The early effects of malignant neoplasms are similar to those of innocent growths in the air passages, namely, dyspnea, cough, and expectoration with hemoptysis

In regard to frequency of hemoptysis in nontubercular disease of the trachea and lungs Jackson and Diamond found the principal causes to occur in the following order of enumeration. bronchiectasis, primary bronchial carcinoma, tracheobronchitis, pulmonary abscess, no evident disease, nonsuppurative pneumonitis, suppurative pneumonitis, bronchial adenomas, secondary pulmonary cancer, primary tracheal carcinoma The manifestations of a pulmonary abscess may be produced, with severe toxemia An extensive growth produces cachexia, pain if spreading into the mediastinum, and dysphagia if involving the esophagus

The physical and roentgenologic examination will reveal the situation of the tumor in most cases, but it is generally necessary to make a bronchoscopic examination, which also affords an opportunity for biopsy

The thin ones of postures 3 and 4 (Fig. 6-1) suffer with the functional disturbances known to affect the visceroptotic type Those who have postures like those of 3 and 4 (Fig. 6-2) are hypersensitive about both their posture and their degree of obesity.

In many families it seems that posture is heritable.

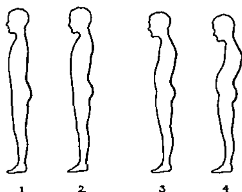

Fig 6-1 Postures of persons of normal or less than normal body weight Posture 1 is excellent, 2 fair, 3 poor, and 4 bad

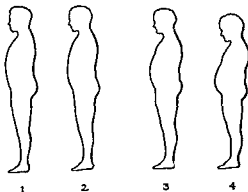

Fig 6-2. Postures of the obese. Posture 1 is excellent, 2 fair, 3 poor, and 4 bad.

Dynamic Posture. Dynamic posture is posture in motion or in action or in preparation for action It includes the transitions between the static positions of lying, sitting and standing and also such activities as pushing, lifting, walking, running, climbing, jumping, dancing, swimming, work and play. Dynamic posture includes the uses of the upper extremities and the trunk as well as of the legs, and the relationships between the various parts of the body in action Dynamic posture includes locomotion, which requires the combined use of all four extremities Poor dynamic postures are characterized by awkwardness and inability of performance and are present in diseases of the central nervous system.

The basic dynamic posture is characterized by a slight crouch, with the ankles, knees and hips flexed, the head and trunk inclined forward and the trunk slightly flexed, the arms relaxed and slightly flexed. With the body in this position the muscles are in a midposition with increased tone, balanced and ready for instant and powerful action in any direction They act also as springs, absorbing shocks and initiating movement

Walking. Walking may serve as an example of dynamic posture. The body is tilted slightly forward from the basic standing position and the weight is thrown on the ball of the foot, while the other thigh is lifted and the leg and opposite arm are swung forward Various muscles, aided by inertia, maintain the body in balance on the ball of one foot until the opposite heel strikes, when the weight quickly advances to this leg with the knee extended Momentum carries the body forward over the extended leg until it passes the perpendicular, when the thrust of the foot renews the action and the process is repeated with the opposite foot and leg (Fig 6-3)

Correct walking is done with a smooth rhythm, the muscles contracting gently with a brief wavelike action and relaxing in the interval. It is characterized by free muscle and joint action, momentum, balance and rhythm Effort becomes much greater if the speed is increased or if momentum and rhythm are disturbed

Alertness, nimbleness, speed, smoothness and steadiness are required for the development of dexterity Dexterity is the requisite for the synchronization of the movements necessary for the performance of proficient and deft walking, especially at a military cadence of 120 steps per minute These attributes are obtained by (1) a heritage of good muscles and (2) a lifetime of careful training and control

6

DISEASES AFFECTING LOCOMOTION

Diseases affecting locomotion interfere with the modes of the body such as posture, gait, equilibrium and often positions while in bed, at rest and during illnesses These modal disturbances result from and are the manifestations of diseases of the skeleton, the peripheral vascular circulation, muscles and nerves

POSTURE

The term posture refers to the sum total of the positions and movements of the body. Static posture refers to the different positions of rest and the variations of these positions Dynamic posture refers to the body in motion or in action It is by means of these postures that the body attains comfort, mechanical efficiency and physiologic function while at rest and during locomotion. Disturbances in posture are frequent accompaniments of diseases affecting locomotion.

Static Posture. Static posture is the posture while at rest. It includes the normal positions for lying, sitting and standing *Lying* is more easily assumed than any other position Static posture may be affected by diseases of the skeletal structures and also by diseases of the heart and lungs.

Sitting. The usual sitting position is with the trunk and head erect and centered over the pelvis or tilted slightly forward, with a medium or slight lumbar arch and with the hips and knees flexed at a right angle The sitting posture may be the only comfortable posture available to those who have congestive heart failure.

Standing. In the standing position the body is vertical and essentially straight when seen from the side as well as from the back. The position is maintained with the spinal column rather than the shoulders The body achieves its full height in this position, with the head and chin level, not tilted back The weight is slightly more on the heels than on the toes, although in the dynamic position of expected forward movement the weight shifts toward the toes. A strong man or woman may faint if required to stand rigidly for a long time (30 minutes or more) because of the relatively static condition of the circulation and the accumulation of blood in the vessels of the lower extremities Ankylosis of both hip joints in extension limits the postures to those of standing and lying

The length of time that a person can stand without fatigue is related, among other factors, to the posture A person of good posture as represented by postures 1 or 2 (Fig. 6-1) can stand much longer without fatigue than a person of poor posture. Postures 3 and 4 (Fig 6-1) represent those of persons who have poor muscle tone from lack of exercise or from disease.

Obesity changes the postural appearance. Those who have good postures such as *postures 1 and* 2 (Fig 6-2) may not be handicapped while they are young However, as age advances, postures 3 and 4 (Fig 6-2) are assumed.

Postures 3 and 4 (Figs 6-1 and 6-2) will not permit proper space for good physiologic functioning of the organs of respiration and digestion Posture is always an important diagnostic consideration in diseases of the heart and lungs.

During youth, if the person is otherwise healthy, poor posture may not be measurably detrimental to the state of health. However, as the years advance, those of poor posture are noticeably more prone to poor health than persons of good posture

shoes, corns, rheumatism, gout, sciatica, metatarsal neuralgia, hip-joint or knee-joint disease or injury (recent or old), sacro-iliac disease, sprains, inflammatory disease of the extremities, short leg and paralysis of one leg, give rise to a limping or hobbling gait. The most characteristic methods of abnormal progression are seen in diseases of the nervous system.

Ataxic Gait. In walking, the foot is raised suddenly and too high, the leg is thrown forward with unnecessary vehemence, and the foot is again brought to the ground heel first, or flat-footed with a stamp The feet are usually planted wide apart, and while they are in the air they move as if the patient were doubtful where to put them. The body is bent forward, and the eyes are fixed on the ground in order to supplement as far as possible the loss of muscular and articular sensation. This gait is extremely characteristic of locomotor ataxia

Cerebellar Ataxic Gait. The manner of progression resembles that of an intoxicated person The patient walks with short steps and with his feet wide apart, staggers, reels, sways to and fro, and reaches a set point by zigzagging toward it. The swaying is relieved if he is supported by the hands of the observer placed under the armpits This gait is significant of a tumor of the vermis or middle lobe of the cerebellum, and is often called the titubating gait, or simply cerebellar ataxia A somewhat similar gait is seen in Friedreich's disease, hereditary cerebellar ataxia, dementia paralytica, ataxic paraplegia, labyrinthine disease and, to some extent, vertigo from any cause.

Steppage Gait. This variety of gait is due to paralysis of the extensor muscles of the foot whereby, when the foot is lifted, its anterior part tends to hang or drop down. In order to prevent the toes catching and tripping against the ground, the leg carries the foot somewhat forcibly forward, raising it at the same time unusually high, thus throwing the toes upward and bringing the foot to the ground heel first Steppage gait resembles the gait of a man who is walking through snow, thick grass or brushwood It is evidence of peripheral neuritis of the anterior tibial nerve, and because of a certain resemblance to the gait of locomotor ataxia, is sometimes termed the pseudotabetic gait

Spastic Gait. The legs are rigid and move stiffly, and there is apparent difficulty in bending the knees In consequence the foot is dragged along, the toes catching and scraping on the ground In some instances, owing to spasm of the adductors of the thigh, the legs and knees touch and cannot be separated, causing cross-legged progression, that is, the legs and feet overlap at each step This gait depends on the excessive tension and spasticity of the muscles arising from lesions of the upper motor neurons. It is therefore, when bilateral, significant of sclerosis affecting the lateral pyramidal columns of the cord. The mode of walking in hemiplegia is a unilateral form of the same gait The paralyzed leg, by a tilting of the pelvis, is swung outward and around to the front, the toes often scraping the ground

Festination. The head and body are bent forward and the patient takes short, shuffling, hurried steps, his speed tending to increase as he progresses, exactly as if he were being constantly pushed forward and were trying to prevent it. This gait is termed festination or propulsion In some instances, if the patient is pulled rather suddenly backward, he will take a number of backward steps (retropulsion), although the body remains in its forward-leaning attitude This gait is characteristic of Parkinson's disease and extrapyramidal neuron disease

Waddling Gait. The shoulders are thrown back, the back is hollowed (lordosis), and the abdomen protuberant, the body sometimes actually leaning backward In walking, the feet are planted wide apart and the body swings from side to side at each step—the waddling or duck gait. It is a very characteristic symptom of pseudohypertrophic muscular paralysis. It is seen also in disease, or congenital dislocation, of both hip joints

over the motive parts involved in dynamic posture. A lack of these attributes may indicate disease

Walking with a limp may result from pain, weakness, stiffness or deformity. Pain may be caused by an injury, such as a sprain, fracture or bruise, a blister, a corn, or an inflammation such as arthritis. Weakness may be due to many things, such as lack of sleep, improper diet, illness, heat and humidity, a poor heart, lung disease or nerve or muscle damage Stiffness may be due to muscle or joint damage, or to tense or contracted muscles. Deformities such as knock knees, bowlegs, short or twisted

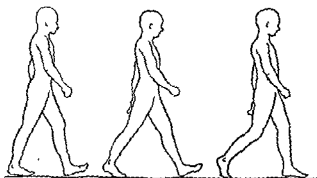

Fig 6-3 Walking Taking one step forward.

legs, clubfeet and high or relaxed arches have their individual effects on manner of walking.

The security of balance and ease of walking or running are enhanced by swinging the opposite arm and leg forward and backward with each step as if in four-footed locomotion. The normal co-ordination of movements of the extremities may be either exaggerated or lost when there is a limp.

Poor Posture. Poor posture may be due to changes in muscle tone or to changes in skeletal structures Irrespective of the cause, a poor sitting posture is characterized by a drooping of the spinal column and trunk, with the lumbar and thoracic portions of the spinal column flexed, the pelvis tilted back, the abdomen and chest flattened and compressed, and the shoulders and head forward A poor standing posture is characterized by a forward movement and tilt of the pelvis, with an increased lumbar lordosis and an increased thoracic kyphosis In this poor standing posture the knees flex, the abdomen sags and protrudes, the chest flattens, and the shoulders, head and neck are advanced. The height is diminished, and the body as seen from the side forms a long S curve.

Muscular Tone. The tone of the muscles has a great deal to do with posture. *There is the large group of persons who have hypotonic muscles and elongated* ligaments with joints which extend too far These hypotonic persons may have weak arches, knock knees, bowlegs, torsion, wryneck, stooped backs, curvatures of the *spinal column, and weak lumbosacral joints, any one or a* combination of which affects posture Any disease or injury which causes tonus changes in the muscles, ligaments or bones is often the cause of poor posture In addition, poor posture may *result from poor training or poor habits*

Gait. The manner of walking is closely associated with the manner of standing. In order to observe the mode of walking, the examining physician requests the patient to walk away *from and back to him, to walk at right* angles to the line of sight, and to walk along a crack between the floor boards or a seam of the carpet.

In pregnancy, ascites, large abdominal tumors, cretinism, pseudohypertrophic [illegible] widely separated so

[illegible]

Painful or [illegible] [illegible] mities, such as tight

fevers, such as typhoid fever, even at an early period, because of the marked muscular weakness and mental apathy so characteristic of typhoid fever. It may be present in motor apathy, which often attends frontal lobe brain tumors.

RIGID DORSAL POSITION IN BED A rigid dorsal position, with both legs drawn up, in order to diminish abdominal tension, is the rule in general peritonitis and in many cases of pelvic peritonitis In appendical peritonitis the right leg alone may be flexed In hip disease also there is flexion of one knee

ON SIDE IN BED. The patient may lie on the side, and the manner of lying may be active or passive, as in the dorsal position There are many persons who cannot rest on one or the other side because of discomfort or actual pain. Often no assignable reason can be found to account for this manifestation of discomfort.

Patients having acute one-sided affections of the thorax usually lie on the affected side to limit its movements and lessen the pain caused by pleural friction, as well as to afford greater freedom of compensatory motion to the healthy side. Moreover, if a large pleural effusion exists, the pressure due to its weight will not burden the heart and the healthy, uncompressed lung when the patient lies on the affected side The posture of a patient with a cavity in the lung is of some significance, that position being chosen which brings the opening of the cavity uppermost, thus allowing secretions to accumulate and be discharged at infrequent intervals instead of constantly trickling into the bronchial tubes and causing an incessant irritating cough. The rule of lateral decubitus is not invariable, since the patient may find other positions preferable In sciatica the subject usually lies on the unaffected side

The lateral position, with the legs drawn up to meet the trunk (the coiled posture), is seen in meningeal, cerebral and cerebellar disease (due to spasm), and in hepatic, renal and intestinal colic

OPISTHOTONOS. Opisthotonos is an uncommon dorsal position in which the body rests on the head and heels, the trunk being arched upward. It is observed in strychnine poisoning, tetanus and uremia, as well as in some peculiar manifestations of hysteria A modification of this position is observed in the characteristic contraction of the posterior neck muscles in meningitis, whereby the back of the head bores into the pillow

EMPROSTHOTONOS Emprosthotonos is an attitude in which the upcurved body rests face downward on the forehead and feet It is the opposite of opisthotonos and is rarely seen, but may be observed in tetanus, strychnine poisoning, paralysis agitans and cerebrospinal meningitis.

THE SKELETON

The diverse activities to which mankind is adaptable are first of all dependent on skeletal design The skeleton is composed of the axial and the appendicular divisions The axial skeleton is, as the name suggests, the center or the axis about which the movements of the appendicular skeleton are resolved.

The *axial skeleton* embraces the bones of the head, the spinal column and ribs, the hyoid bone and the breast bone The spinal column includes the vertebrae of the cervical, thoracic and lumbar regions, and the sacrum and coccyx.

The *appendicular skeleton* embraces the bones of the extremities, including the shoulder girdle or thoracic girdle, formed by the scapula and clavicle, to which the upper extremities are attached, and the pelvic girdle, formed by the innominate bone, to which the lower extremities are attached.

In the four-footed position the appendicular skeleton is concerned only in locomotion In the upright position assumed by man, locomotion is more complex. The upper extremity is freed from its main function of locomotion to follow the will of the brain In order to subserve the hand in the performance of its diverse functions, the back, a part of the axial skeleton, has assumed more elasticity in order that it may bend to carry the hand to its appointed tasks.

Equilibrium. Equilibrium is a state of balance or equipoise; a condition in which opposing forces exactly counteract each other. Clinical histories of those who have sustained injury from sudden loss of lateral equilibrium are common. Lateral equilibrium is often lost while one is carrying a weight in one hand. However, injury to the back may be sustained without a loss of lateral equilibrium if a heavy weight is carried in one hand and the pace is hurried or lengthened.

Lateral equilibrium can be disturbed by a deviation of the spinal column above the sacrum and to one side and also by anything that affects the length of either leg When a position of rest is desired, the hips are moved laterally so that the center of weight falls on one leg, which is kept extended The opposite hip then descends until further adduction is stopped by the superior ligaments of that hip

In order to maintain balance, the movements of the body must be properly performed and a relationship of the parts one to the other must be maintained. This must be true whether the body is in a state of motion or of rest. During motion the muscles control the position of the bones. During rest the position of the bones is controlled by the ligaments. The weight of the body acts as a constant force pressing downward, and it is nicely balanced on the bones by the ligaments, aided by the muscles. A weakness of any one of these three elements, ligaments, muscles and bones, may permit balance to be altered.

If balance is altered, deformity ultimately will result. Distortion of a bone as the result of a badly united fracture throws the weight and muscular action too much to one side, with the result, first, that action of the part is impaired and, second, if use of the part is persisted in, deformity results and increases. If there are relaxation and weakness of ligaments during adolescence and if the ligaments give way in the foot, for instance, flatfoot results, in the knees, knock knee results, and if in the back, scoliosis or lateral curvature If the muscles give way, as in poliomyelitis, deformities result which may have to be corrected, if they can be rectified at all, by the proper application of braces or by tendon transplants.

Mode of Moving. In certain ailments there is unusual *immobility* due to the increase of pain on motion, as in arthritis, scurvy and rachitis, or a disinclination to move because dyspnea is made worse by exertion. Paralysis or tonic spasm of large muscular groups is another cause of enforced quietude

An opposite condition, *restlessness*, exists in many diseases, as in fevers, large hemorrhages and hyperthyroidism. Agitated and irregular movements are seen in chorea, in hysteria, with its manifold manifestations, and in other diseases of the nervous system Severe griping or colicky pain, gallstone colic or renal colic will induce the patient to throw himself about in the hope of relieving his suffering

Posture in Bed. Rest in Bed. The patient usually takes to bed in acute illness or in chronic ailments because of general weakness, pain, or inability to remain up and around In some cases the patients may assume that they are unable to be up, though they do not have pain, weakness or fever. In some special cases there is interference with the use of the limbs, as in certain diseases of the nervous system.

Many persons in health habitually assume certain attitudes while in bed, and their customs in this respect may not be changed by illness. Because of this fact the postures assumed in disease and their diagnostic associations are described as follows:

Static Posture in Bed. In the dorsal strong or active posture the patient lies on the back comfortably and without constraint. This posture is seen in health and in slight illness unattended with great pain

Passive Posture in Bed. In the dorsal inert or passive posture the patient lies on the back but is constantly slipping toward the foot of the bed, thereby putting the body in a posture which is uncomfortable and which interferes with the respiratory movements. The passive posture is observed in conditions of great weakness, most frequently in the acute infectious diseases. It is especially characteristic of severe

fibrous tissue. The disks are attached to the cartilaginous plates of the vertebral bodies and are pulpified centrally to cushion the vertebral column, for instance on jumping and landing suddenly on the feet.

The skeletal muscles control the motion of the back within the limits determined by the ligaments These muscles are arranged in symmetrically opposing groups Posteriorly the short and long intervertebral muscles attached to posterior and lateral processes, the vertebrocostal, vertebro-iliac and vertebrosacral groups are extensors of the back and acting in unison with other groups, rotation and lateral bending are accomplished

The tissues of the back are innervated and nourished by the posterior divisions of the segmental nerves and blood vessels.

Variations and Anomalies of the Vertebrae. Each human vertebra is formed by the fusion of adjacent halves of two primitive somites and passes through membranous and cartilaginous stages to become bone

Irregular fusion of the half somites gives rise to hemivertebrae, a frequent anomaly When it occurs, there is usually a corresponding anomaly on the opposite side of the column a few segments distally which corrects the order of fusion. Though the lesion causes deformity of the back, it is of no great clinical importance

In the human vertebral column the number of segments of the vestigial coccyx and of that part of the sacrum distal to the articulations with the ilia is of no particular consequence. The number of cervical segments is found to be remarkably constant The thoracic vertebrae, distinguished by attachment of ribs, vary in number from 11 to 13, the modal number being 12 The number of lumbar segments varies from 4 to 6 from a mode of 5 There is frequently a gain or loss of one thoracic segment with compensatory loss or gain of a lumbar segment, the total number of presacral segments remaining unchanged Evolutionists aver that in man there has been a progressive shortening of the presacral column which has been synchronous with specialization in skull, brain and teeth

The first sacral segment of the vertebral column is determined by the level at which the ilia articulate with the column to form the sacro-iliac joints These are formed by the approach of the ilia, developing in the limb buds, to conjugate with the vertebrae The meeting is usually, but not always, bilaterally symmetric Lagging of one ilium behind the other results in asymmetric sacralization of the last lumbar or first sacral segment

The partial loss or gain of a segment, as in the case of unilateral or bilateral sacralization of the last free segment with large transverse processes impinging on or articulating with the sacrum or ilium, narrowing of the lumbosacral disk or formation of a false promontory, rarely causes disability

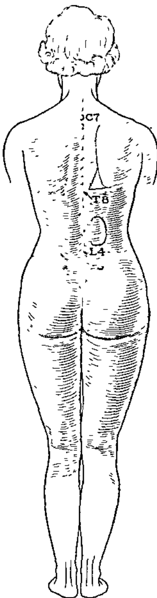

Fig 6 4 Topography of the back C7, seventh cervical vertebra, T8, eighth thoracic vertebra, L4, fourth lumbar vertebra

Defects in closure of the neural canal and in development of the articular processes which anchor the lumbar column to the sacrum may occur In such instances the supporting structures of the sacrum may lie in any position between the sagittal plane characteristic of the lumbar vertebrae and the transverse plane of the sacrum, and frequently these defects vary bilaterally and may definitely affect the stability of the lumbrosacral anchorage. It often predisposes to a forward displacement of the involved vertebra on the segment below. This forward displacement is known as spondylolisthesis.

Skeletal Anomalies. Anomalies of the axial skeleton comprise, first of all, those of the head. These anomalies are great and mainly are incompatible with life. Individuals who survive with head anomalies often have mental derangements (see Complaint, Chapter 2; and Chapter 4). The rest of the anomalies of the axial skeleton are for the most part related to the number and development of the vertebrae and thus will be mentioned in relation to the vertebrae

Anomalies of the appendicular skeleton are related to the extremities. The limbs either may fail to develop at all or may be present as mere rudiments of structure (amelus). Sometimes the proximal segments of an extremity are normal while the distal portion is deficient and tapers to a stump (hemimelus). In the reverse conditon at least the proximal segment is missing and the hand or foot springs directly from the trunk (phocomelus) Union of the legs produces the mermaid condition (sympodia). A number of deformities may be associated when the hands or feet lack digits, for example, split, or cleft, anomaly of the hand and comparable deformities of the feet. Opposite in nature is a partial or complete duplication (dichirus). An example of dichirus is *polydactylism*, which usually is characterized by the addition of but a single digit The bony fusion or fleshy webbing of digits (*syndactylism*) is usually limited to union of the middle and third digits. Abnormal shortness of the digits is *brachydactylia*, due either to the omission of phalanges or to digital shortening The opposite tendency is hyperphalangism, in which supernumerary phalanges are interpolated in the customary digital series. All of these malformations of hands and feet tend to be strongly heritable (Arey).

Clubhand or *clubfoot* may result from primary defects in the differentiating limb buds with malformed muscles.

Congenital elevation of the shoulder results from an arrested descent of the upper limb from its cervical, embryonic position. Congenital dislocation at the hip joint results from failure of the outgrowths that normally produce a brim about the socket floor of the joint *Intra-uterine amputations* (at any level) are due to focal deterioration and not to constrictions by loops of the umbilical cord or amniotic bands (Arey).

THE AXIAL SKELETON AND LOCOMOTION

The Back and Spinal Column. On inspection of the back of a normal person who is undressed and standing erect, a median depression is observed to commence at the lower part of the line of the scalp and to extend almost straight down the back to the sacrum (Fig. 6-4) The prominence of the seventh cervical vertebra and the first thoracic vertebra can be seen. In the middle of the depression the spaced elevations representing the spinous processes of the vertebrae often can be seen and always can be palpated They form an approximately straight line. These prominences end at the beginning of the sacrum

From the superior border of the sacrum, down to near the top of the gluteal folds, is a triangular space with its base above and apex downward. The apex of this triangular space marks the third sacral vertebra. Laterally opposite the second sacral vertebra the posterior superior iliac spine is palpable The elevations limiting the apex of the triangle are formed by the erector spinae muscles.

Laterally from the furrow, in the thoracic region, the projections of the scapulae are visible. If the arms are by the sides, the borders of the scapulae are parallel to the median line. The inferior angle of the scapula is opposite the upper border of the eighth rib The medial angle covers the second rib but its tip is level with the first rib. The twelfth rib usually projects to just beyond the outer edge of the erector spinae muscle. The outer edge of this muscle is marked by a depression separating it from the abdominal muscles in front

On the inner side of the lower third of the posterior edge of the scapula is a small triangle. The upper side of this triangle is formed by the trapezius, its lower side by the latissimus dorsi, and its lateral side by the posterior edge of the scapula. As the lung is nearest the surface at this point, this triangle is often chosen for puncture

The spinal column is composed of a complex arrangement of bones, joints, muscles and fasciae. Between each two of the presacral vertebral bodies is a disk of specialized

poliomyelitis. It is often the result of the contraction of one lung after pleurisy or empyema.

The development of scoliosis shifts the center of gravity from the midline to one side so that it falls nearer to the foot on the side toward which the trunk is inclined than to the contralateral foot (Fig. 6-4). To compensate for this shift of weight, the hips are inclined to the opposite side, and the center of weight is brought by this inclination once more midway between the ankles. However, if the single curve of scoliosis is complete and again reaches the median line, as is usually the case in scoliosis, the center of weight may not be disturbed; and if not, lateral shifting of the pelvis does not occur There are instances in which the curves are so irregular that more of the weight shifts to one side than the other; when this takes place, the pelvis shifts, and the hip on the side opposite to the inclination appears to be higher than the other (Fig. 6-5).

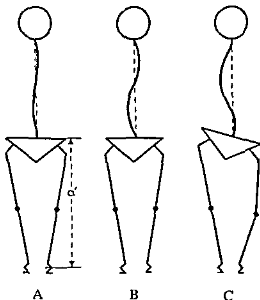

Fig 6-5 Deviations of the spinal column above the pelvis and measurements of the length of the legs

The line joining the two anterior superior iliac spines should be at a right angle with the long axis of the body, as in A and B, before measurements are made

If a hip is ankylosed, its femur is moved laterally, by the examiner, until the line joining the anterior superior spines is at a right angle to the body The opposite femur is made to correspond in position before measurements are made

The line a' (the distance from the anterior superior spine of the ilium to the tip of the internal malleolus of the tibia) when the foregoing conditions have been met gives the length of the leg in question This is compared with the same measurement of the opposite leg

Legs of unequal length cause the pelvis to tilt down on the side of the short leg as in C

Measurement of the Lower Extremities. Under ordinary circumstances, in the absence of deformity or limping, the lower limbs are assumed to be of equal length When on measurement one can detect difference in length of the legs (1 inch or more), there usually is enough deformity to produce unevenness of the gait, for instance a limp (Fig 6-5)

If the legs are of unequal length, the pelvis tilts to the side of the shorter limb, carrying the lower part of the spinal column with it and producing a convex curve, again on the side of the short leg, which is not marked in the lumbar region. The middle and upper parts of the spinal column are carried to the opposite side of the convex curve In patients thus variously affected, the deformities may be great In some the spinal curvature may extend as high as the shoulders and in these the hips may be observed to be uneven in height. The unevenness in the length of the legs may be such that the unequal length is obvious and the gait is markedly limping

Backache and Pain in the Back Without Sciatic Radiation. There is more good evidence to indicate that backache can be definitely associated with misuse and abuse of the back than there is that it results from an upright posture and plantigrade gait. However, it is recognized that the anatomic rearrangements required to change from a pronograde animal to one with an upright posture and a plantigrade gait were extensive From evolutionists (Sir Arthur Keith) we learn that these

More difficult to recognize is spina bifida occulta, in which there is no external mass. The patient may have no complaints or may complain of slight motor, sensory or trophic disturbances in the lower extremities. Over the lower part of the back in the middle line there may be an area of hypertrichosis. On palpation a defect of the vertebral spinous processes in this region may be made out.

At the lower end of the sacrum there is sometimes an abortive tail. This may be a true tail, containing rudimentary vertebrae, sometimes the appendage does not contain bone.

It is generally felt that complete sacralization of the last lumbar vertebra is not a cause of pain, but that partial sacralization of this vertebra produces pain through irritative changes occurring at the site of the false joint. These irritative changes may occur solely in the soft tissues, or eventually they may cause osteoarthritic changes to take place at the site of pseudoarthrosis

Curvatures of the Spinal Column. At birth there are a thoracic and a sacral curve of the spinal column Both of these are convex posteriorly Laterally there is a slight curve in the thoracic region with its convexity to the right or the left, depending on the handedness of the individual

If the height of the two shoulders in the adult is unequal, the lower shoulder usually indicates the handedness; usually the right shoulder is the lower in right-handed individuals A marked difference in height of shoulders increases the chances that a rotary scoliosis is present

The symmetric, or anteroposterior, curvatures of the spinal column are kyphosis, convexity backward, and lordosis, convexity forward An asymmetric or lateral curvature is scoliosis As a rule there are moderate kyphosis of the thoracic region and moderate lordosis of the lumbar region Practically, the lateral curvatures, or scolioses, are the most important of the abnormal curvatures

Curvatures of the spinal column may result from faulty development or may arise from diseases of the spinal column itself. Faults of skeletal development such as supernumerary ribs or absence of a rib may cause scoliosis Spondylitis is often a cause of kyphosis or of scoliosis. Curvatures may develop in the course of Paget's disease, acromegaly or syringomyelia. Ordinarily curvatures of the spinal column depend on softening of the bones of the spinal column due to rickets, early or late, or to osteomalacia

Kyphosis, especially in the thoracic region, is seen in many elderly persons It forms part of the changes which constitute an emphysematous thorax. A kyphotic condition may be present also in rachitic children and in young persons who are weakened by acute or long-continued illness These posterior curvatures are to be distinguished from the more or less sharply angled kyphosis of Pott's disease. In some patients, children in particular, there is a somewhat unusual but normal prominence of the seventh cervical vertebra or the eighth and ninth thoracic spinous processes

Lordosis occurs usually in the lumbar region and is an exaggeration of the normal [illegible] ascites, and [illegible] strophy. [illegible] sociated with orthostatic albuminuria

Scoliosis is a rotary lateral curvature of the spinal column, with prominence of one scapula. If one scapula projects, it indicates the existence of lateral curvature and the existing causative conditions, or paralysis of the serrator anterior muscle on that side. If both scapulae are abnormally projecting, it is probable that the patient has an alar or a pterygoid thorax.

Scoliosis may indicate unequal length of the lower extremities; the habit of standing habitually on one leg or carrying weights on one side; muscular weakness from fever or anemia, or general debility, congenital or acquired. It may also result from the tilting of the pelvis in old sciatica, and from paralysis due to anterior

shows great limitation of back motion. Spasm is present, and percussion reveals localized pain and tenderness over the affected vertebra or vertebrae.

Early in the course of the disease the diagnosis is difficult to make on the basis of the roentgenographic findings; later it is somewhat more easily made. The shadow of paravertebral abscess may indicate an infectious lesion. In general, granulomatous lesions such as tuberculosis cause destruction of bone and cartilage, and the bone has little or no tendency to heal until late in the course of the disease. Active pyogenic infections cause early destruction of bone. Proliferative bone healing occurs readily and there is little actual decrease in the width of the vertebra or interspace.

The differential diagnosis of the infectious organism causing destruction is difficult when there is no history of a preceding disease. Blood cultures may help in the [illegible] tion of the abscess and subsequent bacterial culture and animal inoculation will establish the etiologic diagnosis.

Trauma. In any injury to the spinal column or its structures which has not injured nerves or the spinal cord, the patient walks carefully without jarring. This caution is greatly increased if the sacro-iliac joints have been injured.

In severe soreness of a sacro-iliac joint the gait is suggestive The patient carefully avoids putting weight on the affected side of the pelvis, either while walking or while sitting In the sitting position the weight of the body is maintained on the opposite ischial tuberosity

Strain. Back strain indicates an applied stress greater than that which the supporting elements are normally able to withstand. If the tissues of the back are abnormal at the time of injury, there may be an invasion by an inflammatory process and convalescence may be delayed Soreness, stiffness and weakness persist longer than the seriousness of the injury would justify.

In acute traumatic back strain there is localized tenderness with muscle spasm and pain. The posture will be that of giving way to the injured side in order that tension may be relaxed on the affected side The pain may extend down the back of the hip and thigh, or around to the inguinal region

In back strain the findings of roentgenographic examination are negative.

Flat Back Strain. Flat back strain occurs in the pyknic type of body (Fig. 6-2, posture 4) The strain develops in the lumbosacral region, with lordosis absent in the sitting, standing and supine positions, and with all activities limited by pain which is relieved only when the patient lies supine with the legs outstretched. Stooping forward in the sitting position may be free, but recovery in the upright position is labored and hyperextension is impossible because of pain. The side-lying and the prone positions are uncomfortable The roentgenogram reveals an unusually vertical sacrum

Sprain. The term sprain is applied to a joint that has been suddenly twisted or wrenched, thereby stretching the ligaments until they become torn or separated from their attachments Severe sprains are much rarer than are strains.

After a back sprain there is immediate disability and the symptoms are more severe than in case of strain There may be severe suffering accompanied with nausea and faintness In severe sprain there is muscle rigidity and there is a definitely localized region of deep sensitiveness and tenderness There may be noticeable swelling over the region of the damaged tissues.

A sprain of the back may be expected to heal as quickly as sprained ligaments of other joints, but a residual soreness due to fibrous hyperplasia and often adhesions or scar tissue may prevent work for several weeks after the primary healing has

changes have imparted structural weaknesses. These structural weaknesses, which seem to have commenced in the caudal end of the spinal column, involve most of the muscles and the corresponding nerve centers which control them. In contrast to the weaknesses is the formation of the sacrum, which serves to shorten and strengthen the spinal column

The whole weight of the suprasacral part of the human body is supported erect on the spinal column over long periods of time. The demands on the neuromuscular postural mechanism are even greater in the sitting position than in the standing posture, particularly if the individual sits leaning forward, as in writing or reading The muscles which act on the short levers of the spinal column yield first, while the muscles which act on the long costal levers can still keep on The human being rests these exhausted short spinal muscles by allowing the vertebrae to rotate until the articular processes begin to lock and the transverse processes rest on the neck of the long costal lever Therefore it is more restful, at least for short periods of time, to sit somewhat slumped forward It is an erroneous idea that sitting practically upright is less exhausting.

Backache in the lumbar region, or lumbago, is a common discomfort in those who are acutely or chronically ill and in those who have overworked Backache may be due to causes within the confines of the spinal column, or it may be due to causes situated within the supporting structures of the spinal column. And, finally, it may result from disease of the viscera in the thoracic, abdominal or pelvic regions

Backache is not a disease, only a symptom that may be due to any one of different causes

Postural Backache. The position assumed in poor posture of advanced degrees is familiar to all. The head protrudes, the shoulders are rounded and dropped, the chest is flat, and the thoracic portion of the spinal column has an increased posterior convexity or kyphosis. The lumbar lordosis is exaggerated and the abdomen is protuberant, particularly in its lower half The pelvic inclination is increased Some persons have a flattened lumbar lordosis and compensation takes place by flexion of the hips The knees are slightly flexed and the feet are pronated All degrees of these postural aberrations are encountered

Many people habitually assume, at work or at other times, positions of great mechanical instability, and sooner or later, under the stress and strain, backache results

One common cause of chronic strain in the lower portion of the back is a sagging or protuberant abdomen (Fig 6-2) which, by its weight and its downward and forward pull, tires the muscles and leads to increased tension on the ligaments supporting the lumbar portion of the spinal column. The postural backache of pregnancy is explained on the same basis

The tall, slender individuals with poor posture hyperextend the lumbar regions of the spinal columns. The long, slender type of back is unable to withstand an increased strain for any length of time (Fig 6-1).

Alteration in Plane of Facets. The frequency with which alteration of the plane of articular facets of the lumbar portion of the spinal column occurs is not known. When in the three-quarter roentgenographic view of the spinal column, the facet or facets are found to be placed in a plane that is different from that of the other lumbar facets, the joint cannot move in unison with the remaining joints of the lumbar part of the spinal column; and thus function is impaired and irritative [illegible] of the anomalous articulation may produce pain

[illegible] The blood-borne organisms find vertebral bodies [illegible]. The intervertebral disks are relatively avascular [illegible]ly.

Symptomatically, the patient has a backache which is usually sudden in onset, severe and disabling, along with fever and leukocytosis Objectively, the patient

the shaft of the femur; (5) carcinoma of the rectum, or of the prostate, (6) malignant disease of the female genitalia; (7) the pains of tabes, or of dementia paralytica; (8) ruptured intervertebral disk; (9) intermittent claudication, (10) neuritis of diabetic or other metabolic or nutritional causes and (11) metallic poisonings. However, backache with sciatic extension is most frequently associated with arthritic changes of the lumbosacral joints.

Sciatica (*Sciatic Neuralgia*). Sciatica, or neuralgia of the sciatic nerve, is characterized by pain in the distribution of the sciatic nerve. The causes enumerated in the list of diseases and conditions which may cause backache with sciatic pain are many (*vide supra*). Many of these diseases may be difficult to diagnose. It is for these reasons that the diagnosis of sciatica without a cause is not safe to make However, in practice there are a number of patients who will have sciatica from unknown causes, the idiopathic sciaticas

These instances of the so-called sciatic neuritis or ischemic sciatica (idiopathic sciatica) occur more frequently in men between the ages of 30 and 50 years of age than in women, or than in men of other ages The symptoms commence with pain situated mainly in the back of the thigh The pain is dull and almost continuous with paroxysms of sharp pain and burning The nerve is tender on palpation.

There are other neuralgias of the lower extremity, for instance those of the femoral nerve (anterior crural neuralgia), the external cutaneous femoral nerve (meralgia paraesthetica) or the obturator (obturator neuralgia).

Meralgia Paraesthetica. This is a variety of pain localized in the area of the distribution of the external cutaneous nerve on the lateral side of the thigh. The pain is often induced by standing or walking Obese middle-aged men are more commonly affected than are women The presence of an area of impaired sensation indicates a neuritis rather than a neuralgia Bilateral pain has been observed.

Sciatic Scoliosis. Ellis employs the term sciatic scoliosis to designate lateral deformity of the trunk secondary to a painful minor lesion in the lower part of the back, the buttocks or the sciatic nerves The characteristic lateral tilt of the trunk represents a posture which will relieve or mitigate the pain producing the syndrome.

The etiology of sciatic scoliosis is variable and may be difficult to elucidate. When the cause is a lumbosacral pathologic change, there is a rather sharp lateral deviation of the lumbar portion of the spinal column at the lumbosacral junction without any pelvic rotation.

In spinal arthritis and sacro-iliac disease there may be a generalized bending of the lumbar portion of the spinal column without rotation and deviation. If bending of the lumbar vertebrae is great enough, the scoliosis may be compensated for by a slight tip of the pelvis upward on the side toward the convexity, and the leg on the affected side may be flexed at the hip and knee.

A myelogram may be required to eliminate the possible presence of a protruded intervertebral disk

Traumatic Sciatica. Woltman recorded 77 cases of neuritis of the lumbosacral plexus in each of which there was sciatic pain In 11 of these cases the neuritis was due to trauma, such as excessive flexion of the thigh, hyperextension of the thigh during a dive, fracture of the sacrum, football injury, or a fall from a horse

During sleep a postural injury of the nerve may occur When the lower extremities are compressed in some unusual position, as over the edge of a bed-rail, whether the pressure injures the nerve fibers or the nutrient vessels of the nerve trunk is conjectural

Other Forms of Backache. Other, less severe and some less common, types of pain in the back that occur often enough and present enough similarities to justify mentioning are nocturnal backache, the backache that accompanies menstruation and postmenopausal osteoporosis, and the so-called interspinous ligament syndrome.

taken place. A period of more than 7 weeks should arouse suspicion of superimposed disease, such as arthritis or ruptured intervertebral disk, or of malingering.

Results of the roentgenologic examination are negative.

Muscle Rupture. When a muscle ruptures, a distinct gap can be felt between the retracted ends of the torn muscle and there is immediate disability consisting of local pain, loss of power, and swelling. Such a condition does not often occur in the spinal muscles.

Shoveler's Disease. Wetzel directs attention to the occurrence of avulsions of the spinal processes in the course of exertions, such as pitching hay in farm work, by persons who are unaccustomed to hard physical labor. The complaint is pain between the shoulder blades. There is sensitivity to pressure in this region, and forward and sideward lifting of the arms causes pains. The diagnosis is established by roentgenologic examination. Such patients should refrain for about 4 weeks from the exertion that caused the avulsion.

Degenerative Changes of the Vertebrae. The lumbosacral region is affected by degenerative changes to a greater extent, and at an earlier age, than the other regions of the spinal column, the cervical region being the next most susceptible.

Degenerative changes cause most of the backache in the lower portion of the lumbar segment, where stress is greatest. Degenerative changes are designated as wear-and-tear changes, osteoarthropathy, bony spurring and narrowing of the intervertebral disk

Degenerative changes in the spinal column are not limited solely to the bones. Degenerative changes occur in the skin, the subcutaneous fat, fascia, muscles, ligaments, tendons, bone and cartilage. The muscles soon lose their elasticity and ability for rapid co-ordination. The ligaments surrounding and supporting the spinal column degenerate more rapidly than the muscles. Changes in the vertebrae follow changes in the soft tissue

LUMBAR OSTEOARTHRITIS. In arthritis of the joints of the lumbar portion of the spinal column, pain may appear suddenly, as in lumbago, while the patient is stooping or in some disadvantageous position. Certain positions in sitting are avoided unless the lumbar portion is supported. The pain is intermittent and is characterized by acute exacerbations

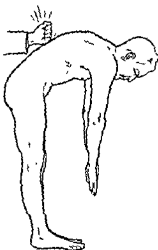

Fig 6-6. Percussion of the back

Examination usually reveals that the patient has evidence of lumbar joint disease and a superimposed myositis. The myositis accounts for the acute exacerbation Local tenderness may exist on either side close to the spinous processes or in the interspinous ligaments Percussion may localize the soreness definitely (Fig 6-6) The roentgenogram may not corroborate the clinical findings, since arthritis can seldom be visualized by the time the first symptoms appear.

Backache and Pain in the Back With Sciatica. Backaches may or may not be accompanied with extension of pain to the sciatic nerve and its distribution.

The term sciatica describes a chronic and often remittent pain situated low in the back which extends down the course of the sciatic trunk in the back of the thigh The pain may extend to the distribution of the external peroneal nerve to the lateral surface of the calf and finally to the foot

Some of the causes of the symptom, backache thus: (1) trauma; (2) rheumatoid arthritis and the cervical, or of the lumbar vertebrae, and dise: (4) malignant disease of the pelvic bones or vertebrae, or chronic osteomyelitis of

Nevertheless, the findings are constant and characteristic enough so that a presumptive diagnosis can often be made before intraspinal roentgenographic studies are made.

The diagnosis is made from properly interpreted spinograms. Love and Walsh warn of the danger of missing a protrusion of the disk on roentgenologic examination after injection of radiopaque oil unless the lumbar portion of the spinal column is kept in extension.

Malignant Metastasis to the Spinal Column. Pain is the first symptom It is almost always limited to definite segments supplied by the nerve roots passing outward through the foramina formed by the involved vertebrae The pain is aggravated by coughing, sneezing, yawning, straining at stool, bending movements of the spinal column or sudden jarring of the body.

The sufferer with metastatic lesions is reluctant to move or turn in bed because motion aggravates the pain Patients who have metastatic lesions of the spinal column are likely to walk the floor to avoid lying down Lying down often aggravates the pain

A common manifestation of metastasis of malignant disease to the spinal column is sciatica. Any sciatic pain occurring in a middle-aged patient; either unilaterally or bilaterally, which is not relieved by aspirin, arouses the suspicion of spinal metastasis.

A significant finding in those who have metastasis to bones is an elevated alkaline phosphatase content of the blood serum. In metastatic lesions of bone which result in increased, localized calcification (increased osteoblastic activity) the serum phosphatase levels are almost always elevated With destructive (osteoclastic) lesions, while the serum phosphatase values may be normal, they are frequently elevated

The diagnosis is suspected from the history and the examination Roentgenologic studies are of diagnostic value when two types of lesions are encountered. (1) evidence of increased osteoblastic activity, as indicated by localized areas of increased density due to increased calcification, (2) localized rarefaction, indicating increased osteolytic and osteoclastic activity with decalcification Increased concentrations of serum phosphatase are of diagnostic value.

History of Backache. It is essential to know (1) whether the pain in the back followed injury or unusual physical exertion, (2) the exact location of the pain, (3) whether the pain is continuous or recurrent, (4) what makes the pain worse, (5) what relieves the pain, (6) whether the pain is getting worse and (7) whether a lawsuit is pending or anticipated It is unfortunate, but nonetheless true, that this last question has to be included If there is litigation pending (and frequently the patient is reluctant to admit it) it is essential that full details, to include names, places and time, be obtained and be made a part of the written record.

Patients who complain of disabilities associated with the back have pain of one of two types, either static pain in the back or pain which recurs and lasts for periods of days or weeks with or without sciatic extension.

Static pain, the commonest of backaches, is brought on by use or physical activity, and it is relieved by rest Its presence denotes some fault in the moving parts of the back, either posttraumatic or due to degenerative disease of the joints There may be a congenital anomaly, or the back pain occurs in the absence of any demonstrable pathologic condition In these latter cases the pain is commonly due to poor postural attitudes which mechanically put undue stress on the ligaments, muscles and small joints of the back Static type of pain is usually present daily and does not vary in intensity except as the intensity of the physical activity varies As a rule, there are no severe acute episodes and there are no complete remissions. Static pain in the back may at times be accompanied by some degree of fibrositis, and the patient describes stiffness on arising, jelling with inactivity, or exacerbation

Of these backaches it is well to know that the backache which accompanies menstruation is rarely due to disease. If it is due to disease at all, the disease is intrinsic to the structures of the back or pelvis and proper examinations may detect the situation of the defective structures responsible for the pain.

Injury Involving the Spinal Column. When an injury of the spinal column has occurred, it is important, first of all, to determine whether or not the spinal cord or the spinal nerve roots have been injured This necessitates a study of the motility, the sensibility, and the reflexes (deep, superficial, pupillary and sphincteral). Should a neural disturbance be found, its exact site must be determined. The site of the vertebral injury causing the symptoms can then be deduced from the interpretations by a roentgenologist.

Protruded Intervertebral Disks. In recent years it has been demonstrated that protruded intervertebral disks are common causes of intermittent backache. The disks are ruptured by a sudden twist of the spinal column from a fall, or by other injury of the spinal column Rupture of a disk may occur also as a part of degenerative disease of the vertebrae A disk may be ruptured or protrude in any region of the spinal column from the first cervical vertebra to the last lumbar vertebra. However, rupture most commonly occurs in the lumbar region

The symptoms are characterized by episodic backache which usually comes on during back motion The pain is often incapacitating for a week or 10 days and then subsides. A recurrence of the pain is to be expected at some future date

During the attack coughing, sneezing and blowing the nose or straining accentuates the pain in all instances During the interval between the attacks there is no distress During an acute episode the patient cannot stand erect or sit comfortably and the pain may be worse at night than during the day These patients may or may not have pain in the leg However, pain is usually present in the leg and it may vary from a simple overflow of localized low back pain into the buttock to severe root pain that extends all the way down the leg into the toes There may be accompanying alterations in sensation, and paresthesias at times Rarely, there is some weakness or paralysis of peripheral muscles, and more rarely some interference with function of intestines or bladder

In the standing position there is often a true sciatic and disk scoliosis which presents as a bend principally affecting the lumbar vertebrae, and the shoulders are maintained at the same level by means of elevation of the pelvis on the affected side, [illegible]

an exacerbation of symptoms

Manipulation of the back in the sitting position may elicit little or no pain on rotation or lateral motion while the spinal column is flexed, but when it is hyperextended and these motions are repeated, all are painful Love and Walsh explain this symptom by their observation that the herniated disk is likely to be reduced by flexion of the lumbar portion of the spinal column, whereas hyperextension, on the contrary, causes the disk to protrude more markedly

The Achilles reflex, which subserves the fourth and fifth lumbar and first and second sacral segments of the spinal cord, is lost or diminished in more than one half of cases of disks at the lumbosacral junction Protruded disks at the fourth interspace are found to reduce the Achilles reflex in some cases, but protrusion at the third lumbar interspace decreases the ankle jerk in one half of these cases. The [illegible] of the [illegible] disk

is present at the third lumbar [illegible]

There are no physical, neurologic or orthopedic signs which are found in all cases of protrusion of intervertebral disks that are characteristic of this injury only.

MENSURATION. Measurement of chest expansion is indicated when ankylosing spondylitis is suspected. Measurement of the length of the legs may reveal a shortening which is influencing the spinal mechanics. The calves should be measured at their greatest circumference and the thighs at comparable measured levels below the anterior superior iliac spines.

The Sitting Position. Have the patient sit on a stool without a back, so that the feet rest comfortably and squarely on the floor. Observe the lumbar region for evidence of whether or not the weight is borne equally on the two ischial tuberosities. A manifest desire to sit on one ischial tuberosity and complaint of pain when asked to sit squarely on the stool arouse the suspicion that there is lumbosacral, sacro-iliac or coccygeal soreness.

If the normal lordosis of standing persists while sitting, the curvature may be at a higher level than usual because mobility of the lumbosacral joints is deficient, or it may be at the lumbosacral junction, as in spondylolisthesis

The Supine Position. An examining table long enough for the patient to lie at full length or one adjustable to full length is better than a shorter, higher table. If a stool is used to climb to the table, a patient with a unilateral back lesion will step up on the good leg

Ellis makes the following observations on patients as they get on the examining table. A diffuse tenderness in the lumbar region will cause the patient to crawl onto the table in the prone position and then roll over with some difficulty A patient who has coccygodynia objects to lying flat on the table. A patient who first sits on the examining table and then turns around so that a leg may be supported with his hands in bringing it up on the table is protecting a unilateral lesion on the side of the supported leg A lumbosacral or sacro-iliac soreness may prevent lying flat on the back on the table Lying is more comfortable if the leg and back are rotated slightly toward the painless side. The insistence on slight flexion of the hip while lying is more suggestive of sacro-iliac than of lumbo-sacral soreness Observe whether or not lordosis is changed by the patient flexing the hips and knees In lumbosacral soreness the lumbar lordosis does not change; in sacro-iliac soreness the lordosis is effaced

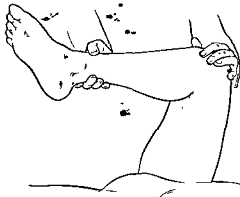

Fig 6-7 Internal rotation of hip joint is free of pain in the absence of disease of the hip

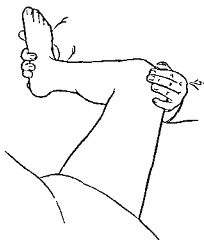

Fig 6-8 Lateral rotation of hip is free of pain in the absence of disease of the hip

Application of pressure on the knee during this manipulation with production of pain is a positive Laguere's sign (see text)

during cold, damp weather. The fibrositis in these instances is secondary to the underlying condition responsible for the pain, and is not the syndrome of primary fibrositis.

The recurring or intermittent type of pain in the back comes on in acute attacks. The attacks occur suddenly while the back is in motion. The pain may be incapacitating, may last from 5 to 10 days or more, and may recur 2 or 3 times annually. Such symptoms are commonly produced by protrusions of intervertebral disks, tumors of the spinal cord, spondylitis due to either tuberculosis or brucellosis, benign lesions or metastatic neoplastic conditions of the vertebrae.

Examination of the Back. The patient is examined in the standing, the sitting, the supine and prone positions Inspection of the normal back has been described (p. 186).

The Standing Position. The examination of the back begins by desiring the patient to walk, if walking is possible without too much pain. The examiner observes the manner of station and gait. The patient is then asked to sit down, take off the shoes and stockings. performance of these tasks also is observed. The patient who has a painful back moves carefully and with evidence of stiffness.

Usually the tilt of the trunk is away from the painful side in sciatic scoliosis, but occasionally it may be toward that side Observe whether or not there are flattening or the lack of lumbar lordosis, ankylosing spondylitis, prominent spinous process of the fifth lumbar vertebra in spondylolisthesis, angular kyphosis of Pott's disease, rounded dorsal kyphosis of Scheuermann's disease, and atrophy of the calf

MOTIONS OF THE SPINAL COLUMN The motions of the spinal column are extension, flexion, rotation and lateral bending The ranges of these motions are determined while the knees of the patient are held straight

A limitation in flexion of the spinal column in the standing position should be compared with the range of motion at which the pain appears when these same motions are performed when the patient is sitting normally upright.

Lateral motion in the lumbar region is confined to an arc of not more than 40 degrees. The extent of active and passive lateral motions is compared with this normal range. The lateral motions of the lumbar vertebrae are better observed with the patient in the sitting position than in the standing position In the standing position spasm of the tendons bounding the popliteal space may cause a limitation of motion

Flexion and extension are free movements of the neck and lumbar regions. Rotation is free at the articulation of the axis with the atlas. It is limited in the midcervical region, freer in the upper portion of the thoracic region, gradually diminishes downward, and is absent in the lumbar region.

The degree of referred pain, if any, on each motion is significant as an aid to the localization of disease On flexion the patient will stoop toward the side of the spastic erector spinae group of muscles, which is ordinarily toward the side of the pain

Record should be made as to which of these motions, if any, reproduces the pain of which the patient complains. In the matter of forward flexion one should distinguish between movement in the spinal column itself and movement accomplished by flexion at the hip joints

PALPATION. Palpation and percussion over the spinous processes, lumbosacral and sacro-iliac joints should be carried out. The amount of spasm of the paravertebral muscles is estimated. One should ascertain whether or not there is tenderness on pressure over the sciatic notches or over the sciatic nerve itself in the thigh. In fibrositis the demonstration of palpable tender nodules is diagnostic.

PERCUSSION. Percussion of the back is usually performed with the closed fist (Fig 6-6).

LASÈGUE'S SIGN. The (modified) straight leg-raising sign of Lasègue is elicited by elevating the limb with the knee extended. Approximately the first 20 degrees of this motion produces flexion of the hip and may produce pain in the hip joint. As the motion continues and a pull is exerted on the ischial tuberosity by the hamstring muscles, rotation is exerted on the sacro-iliac joint When the leg approaches a vertical position or points straight upward, torsion increases rapidly and begins to be strongly transmitted through the lumbosacral joint of the same side. At right angle flexion even soreness in the opposite lumbosacral joint will begin to be manifest.

In sciatica, if the straight leg test is performed to the point where pain begins, sudden dorsal flexion of the ankle will greatly aggravate the symptoms (Fig. 6-12).

LAGUERRE'S SIGN This sign is elicited by flexion, abduction and outward rotation of the hip These movements force the femoral head against the anterior portion of the capsule, and pain results if there is hip-joint disease. This test is used to distinguish psoas spasm, hip-joint disease and sacro-iliac disease from lumbosacral disease (Fig. 6-8)

GAENSLEN'S SIGN Gaenslen's test is used to elicit soreness in the sacro-iliac joint.

the table with the knee flexed Pain is produced by rotation of the sacro-iliac joint of the hyperextended leg

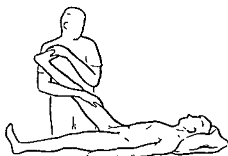

Fig 6-12 Lasègue's test Straight leg-raising test with knee kept extended while pressure is applied to the foot

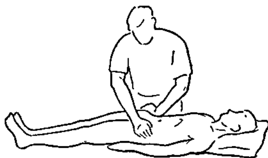

Fig 6-13 Sacro-iliac tenderness demonstrated by downward pressure on the iliac crests.

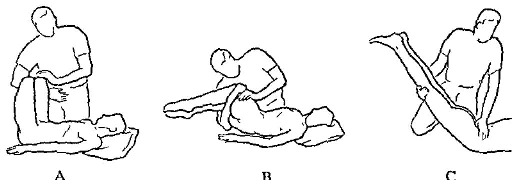
able range, so that, when pain begins in the lumbosacral region, as soon as flexion begins, sooner than when either leg is raised separately, the suspicion of disease rests on the lower lumbar portion of the spinal column and lumbosacral joints rather than on the sacro-iliac joint and the sciatic nerve



the flexed knee down

BAER'S SACRO-ILIAC POINT OF TENDERNESS Before concluding the examination in the position for eliciting Patrick's sign, palpation should be made deeply in each lower quadrant of the abdomen to elicit Baer's sacro-iliac point of tenderness, which is described as situated 2 inches from the umbilicus on a line between the umbilicus and the anterior superior iliac spine Sacro-iliac tenderness may also be elicited by downward pressure on sacro-iliac spines (Fig 6-13)

The Prone Position. When it is possible for the patient to lie in this position, the examination should be continued as an inspection to estimate (1) the amount of lateral deviation as compared with that present in the standing and sitting positions, if any exists, and (2) the degree to which such distortion of the spinal column

HIP MOTION. When the knee is flexed, motions of the hip joint can be studied without the transmission of tension to the sacro-iliac or the lumbosacral joints. Any complaint on internal or external rotation at the hip *with the hip and knee flexed* directs suspicion to the hip joint itself. The motions of the hip joint may be tested as shown in Figures 6-7 and 6-8

Lateral and rotary motions of the lumbar portion of the spinal column, while the hips and the knees are flexed, are performed by the examiner pressing the knees forward, laterally and downward as desired (Fig. 6-9). Passive flexion of the lumbar

Modified from Ellis, J. D., *The Injured Back and Its Treatment*, Charles C Thomas 1940

Fig 6-9 A, flexion and rotation of the hips may identify lumbosacral soreness as well as the extent of spasm or contraction in sciatic scoliosis In acute injury of a sacro-iliac joint compressive force (forceful flexion of both hips) is not so painful as axis traction or separation

B, in lumbosacral joint disease strain on the sacro-iliac joints, exerted as shown, elicits tenderness in the lumbosacral joint.

C, fixing the spinal column and hyperextending the legs permit observation of the position at which pain begins The force acts successively on the lumbosacral junction, the sacro-iliac joints and up the spinal column as the point of fixation is moved upward

joints can be performed through a larger arc with less pain in the supine position than in the standing or the sitting position. Compression of the anterior superior spines of the ilia toward each other and separation from each other as tests for sacro-iliac disease are performed in this position. In sacro-iliac disease these two maneuvers cause a complaint of pain

The straight leg-raising tests are most valuable in detecting disease of the sacro-iliac joint and disease of the lower lumbar region of the spinal column (Figs. 6-10 and 6-11).

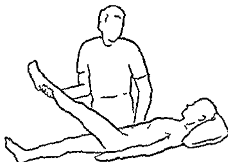


Fig 6-10 Straight leg-raising test Hip free. This much flexion at the hip is usually without pain when *the hip is not diseased*

Fig 6-11. Straight leg-raising test with hip held down Less flexion at the hip is permissible without the production of pain when the hip is *held down than when it is free*

nates in the subclavian vein, which lies to the inner (anterior) side of the artery.

Immediately below the clavicle is a depression, the infraclavicular fossa. On the sternal side of this depression can be felt the first rib. Since ribs are not always easily identified, it is best, in counting them, to locate the angle of the sternum (angle of Ludwig). The second rib is immediately opposite this angle The angle of the sternum is about 2 inches (5 cm) below its upper edge. Attached to the lower edge of the inner half of the clavicle is the pectoralis major muscle, and to the outer third, the deltoid muscle

Only a small part of the lower edge of the clavicle is free from muscular attachments This muscle-free edge forms the base of the *subclavicular triangle*, and its two sides are formed by the adjacent edges of the pectoralis major and deltoid muscles. This triangle marks the course of the underlying first portion of the axillary artery with the vein and the cords of the brachial plexus of nerves. Deep pressure appropriately applied here can compress the axillary artery against the second rib, but not so effectively as above the middle third of the clavicle. The pressure on the artery is immediately manifested by tingling along the inner side of the arm

Just to the outer side of the junction of the middle and outer thirds of the clavicle, in front of the deepest part of the concavity, is the coracoid process of the scapula It is best felt by pressing the fingers flat on the surface. Running from the coracoid to the acromion process is the sharp edge of the coraco-acromial ligament.

Beneath the acromion process, but covered by the deltoid, is felt the greater tuberosity of the humerus If the arm is placed alongside the body with the palm facing forward, a distinct groove can be felt to the inner side of the acromion process. It is the bicipital groove of the humerus for the long tendon of the biceps muscle. The greater tuberosity of the humerus projects beyond the acromion process and forms the prominence of the shoulder On rotating the arm, the greater and lesser tuberosities of the humerus can be distinctly felt moving under the deltoid muscle

The acromion process of the scapula posteriorly forms a distinct angular prominence where it joins the spine of the scapula This prominent angle can be seen and felt and is used as a landmark for measuring the length of the humerus The spine of the scapula ends at the posterior border of the scapula This border is opposite the fourth rib and the third thoracic vertebra With the arm to the side, the lower angle of the scapula lies over the seventh interspace

THE SHOULDER

Muscles. The shoulder embraces two sets of muscles one set connects the shoulder girdle with the trunk, and the other, the humerus with the shoulder girdle

Movements. The main movements of the shoulder girdle are anteroposterior, as in swinging the arm, those of abduction and adduction, as in raising and lowering it sidewise, and rotary

Functional Testing of the Muscles of the Shoulder. *Deltoid* The examiner, standing in front of the patient, requests the patient to raise the arms laterally to a horizontal position Inability to do so indicates deltoid paralysis Also the deltoid muscle may be conveniently tested as shown in Figure 6-14. (Circumflex nerve supply, C_5, C_6)

Pectoral The examiner stands in front while the patient stretches out the arms straight in front: the examiner then approximates the patient's hands against resistance of the pectoral muscle Paralysis is indicated by failure of contraction.

The two parts of the muscle are tested the sternocostal part as depicted in Figure 6-15, and the clavicular part, as in Figure 6-16. (Lateral and medial pectoral nerve supply, C_5, C_6)

Latissimus Dorsi The patient raises the arms laterally to a level, then, while keeping them fully extended, brings them downward and backward, as if to make

can be corrected after attempting to pull down the leg on the concave side of the lumbar curve.

Roentgenograms. No examination of the back is complete without anteroposterior and lateral roentgenograms of good quality. A localized lateral roentgenogram of the lumbosacral joint is necessary when a lesion at this site is suspected. In fact, when the nature of a lesion is doubtful, localized anteroposterior and lateral roentgenograms of any part of the spinal column are indicated. Oblique views are useful when one suspects a lesion of the articular facets or open neural arches in cases of spondylolysis and spondylolisthesis. When a lesion of the sacro-iliac joint is suspected, stereoscopic anteroposterior roentgenograms of the pelvis will give the most information.

Patients with ruptured intervertebral disks may require myelographic examination.

SUMMARY OF BACKACHE

Many backaches are left unexplained after all examinations have failed to reveal disease. Most persons who have these unexplained backaches continue to live normal active lives despite the back pain.

Perhaps the two commonest ailments to cause soreness and pain in the back are fibrositis and psychoneurosis In women backache is rarely due to disease of the pelvic organs

In a patient known to have malignant disease, an unexplained backache, especially if there is sciatic distribution of the pain, or extension of pain to the leg, excites the suspicion that the cause of the pain is metastasis to the spinal column

In a middle-aged person the onset of a backache with sciatic distribution which is not relieved by aspirin excites the suspicion that there is metastasis to the spinal column from an unknown malignant source The suspicion is strengthened if there is bilateral distribution of the pain

THE APPENDICULAR SKELETON AND LOCOMOTION

THE SHOULDER GIRDLE (CINGULUM EXTREMITATIS SUPERIORIS) AND THE UPPER EXTREMITY

Topography and Bones. The shoulder girdle projects the arm well out from the trunk by means of a framework which consists of three bones the clavicle and scapula superiorly, and the humerus inferiorly. These bones form the basis of the shape and topography of the shoulder. The shape may be modified by the muscles and fat

The clavicle is subcutaneous and can be felt throughout its length. The medial end normally projects above the upper edge of the sternum, which can be felt at the suprasternal notch A prominent ridge marks the outer extremity of the clavicle, if this ridge is difficult to recognize, as is often the case, the examiner continues directly laterally to the point of the shoulder, which is formed by the tip of the acromion process This point having been recognized, the end of the clavicle is found directly mediad from it.

In the median line above the sternum is the suprasternal notch. Just to each lateral edge of the notch is the prominent sternoclavicular joint. On the right side this joint marks the ending of the innominate artery and the commencement of the right common carotid and subclavian arteries That on the left marks the left carotid with the subclavian directly to its outer side and a little posteriorly.

The medial two thirds of the clavicle is convex anteriorly. The lateral third of the clavicle is convex posteriorly, and from its superior surface the trapezius muscle can be felt. Just above the clavicle in the neck and behind the clavicular origin of the sternocleidomastoid muscle is seen the external jugular vein. It termi-

scapulae as close together as possible (Fig 6-21). (Accessory nerve supply, C_3, C_4.)

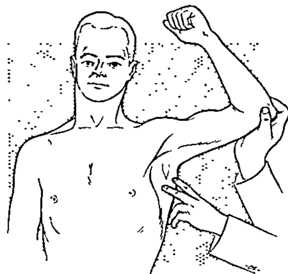

Fig 6-17 Latissimus dorsi muscle (insertion) Standing or sitting with the arm horizontally and laterally extended Attempts are made to extend the arm against resistance The muscle can be seen and palpated with the middle finger Nerve supply C_6, C_7, C_8

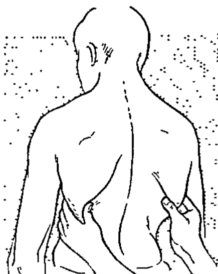

Fig 6-18. Latissimus dorsi muscle (posterior portion) Standing or sitting. On coughing the muscle can be felt except in extremely obese persons. Nerve supply C_6, C_7, C_8

Rhomboideus Muscles. The patient moves the shoulder backward against resistance (Fig 6-22) (Nerve supply, C_4, C_5)

Supraspinatus Muscle Standing with the arm by the side, attempts are made to abduct the arm against resistance. The muscle can be felt on top of the shoulder (Fig 6-23A) (Suprascapular nerve supply, C_5)

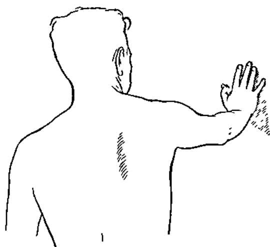

Fig 6-19 Serratus anterior muscle While standing with hand against wall, patient pushes forward. The medial border of the scapula remains close to the thoracic wall, which can be seen or felt Nerve supply C_5, C_6, C_7

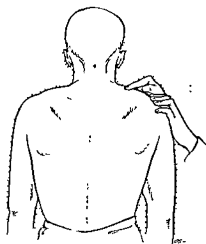

Fig 6-20. Trapezius muscle (upper part) Standing or sitting Attempts are made to elevate the shoulder against resistance The midportion of the muscle can be seen and felt Nerve supply C_3, C_4 (accessory nerve, eleventh cranial)

the hands meet behind the sacrum. The examiner stands behind the patient to resist the movement The muscles are also conveniently tested as the patient tries to adduct the horizontally and laterally extended arms against resistance (Fig 6-17). If the

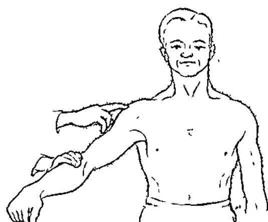

Fig 6-14. Deltoid muscle. Standing or sitting *Attempts are made to maintain an* angle of abduction of the arm of more than 15 degrees against resistance The muscle can be seen and felt Nerve supply C_5, C_6 (circumflex nerve)

patient coughs, the muscle bellies can sometimes be seen and palpated (Fig 6-18). (Nerve supply, C_6, C_7, C_8)

Serratus Anterior Request the patient to push with his hands against the wall If the serratus has lost its power, the scapula will project, and the digitations of the muscle, which should be visible, will not be seen (Fig. 6-19). (Nerve supply, C_5, C_6, C_7.)

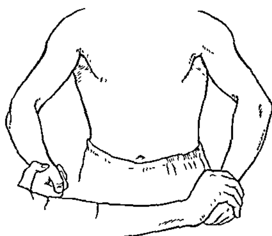

Fig 6-15. Pectoral muscles (sternocostal portion) The patient standing or sitting. The arms are raised below the horizontal Attempts [illegible] the arms against resistance [illegible]

pectoral nerves)

Fig 6-16 Pectoral muscles (clavicular portion) Standing or sitting *The* arm is raised above *the horizontal* and forward flexed at the elbow *Attempts* are made against *resistance to* abduct the arm The clavicular and usually the costal parts of the muscle are evident. Nerve supply C_5, C_6, C_7, C_8 (lateral and medial pectoral nerves).

Trapezius. The examiner asks the patient to raise the shoulder upward against the pressure of the examiner's hand. This will demonstrate the strength of the upper part of the trapezius (Fig 6-20). The examiner asks the patient to bring the

other causes for shoulder pain. Some of these causes are intrinsic while others are extrinsic and these may be enumerated as (1) arthritis (rheumatoid and osteoarthritic, tuberculous and due to pyogenic infections), (2) tumors and infections of the scapula or head of the humerus, (3) lesions of the clavicle, (4) lesions of the acromioclavicular joint, (5) tumors of the soft tissues about the shoulder, (6) fractures or fracture dislocations of the shoulder and (7) diseases of the diaphragm, which often cause pain in the shoulder.

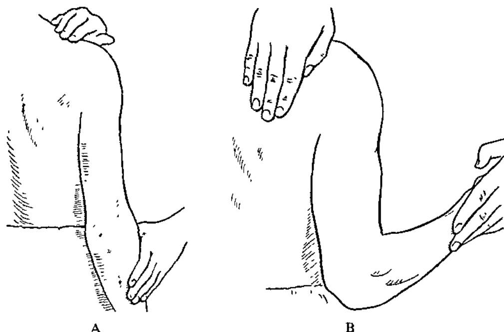

Fig 6-23 A, supraspinatus muscle Standing with arm by the side, attempts are made to abduct the arm against resistance The muscle can be felt on top of the shoulder Nerve supply C_5 (suprascapular nerve)
B, infraspinatus muscle Standing or sitting with the elbow flexed to the side, resistance is made against attempts to rotate the arm externally at the shoulder joint The muscle can be felt Nerve supply C_5, C_6 (suprascapular nerve)

The differential diagnosis of lesions of the shoulder from lesions of the cervical portion of the spinal column or brachial plexus often is difficult It is recalled that in cases of pain in the shoulder or arm, lesions of the cervical part of the spinal column and shoulder joint may be present The most important point in differential diagnosis is the presence of local signs in the shoulder, that is, both active and passive limitation of motion, either diffuse or localized tenderness; atrophy of variable severity, and swelling or local heat in an occasional case of acute bursitis. In cases in which the shoulder joint is free of all of these signs, the primary cause of the trouble usually is elsewhere The pain is referred pain

A number of lesions of the thorax and a few of the abdomen which irritate the [illegible]

erred

pain

Lesions of the superior pulmonary sulcus adjacent to the brachial plexus or sympathetic chain also may cause pain of the arm. Pancoast described a syndrome including roentgenographic shadow [illegible] tumor at the apex of the lung, a neuritic type of pain of the arm, atrophy of [illegible]scles of the hand and arm and Horner's syndrome The *Pancoast syndrom*[illegible] a distinct clinical entity, since neuro-

Infraspinatus Muscle. Standing or sitting with the elbow flexed to the side, resistance is made against attempts to rotate the arm externally at the shoulder joint. The muscle can be felt (Fig. 6-23B). (Suprascapular nerve supply, C_5, C_6)

MONARTICULAR DISORDERS

These affect, intra- or extra-articularly, a single shoulder, elbow, hip or knee.

The Shoulder and Monarticular Disorders. The etiologies of the monarticular involvements, the syndrome or syndromes of arm pain and their relation to lesions of the cervical part of the spinal column, shoulder and brachial plexus are not always possible to delineate and to elucidate.

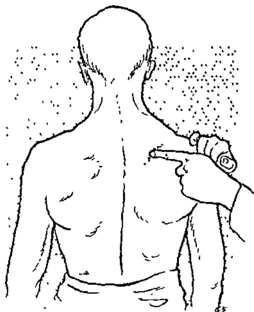

Fig 6-21 Trapezius muscle (adductor scapulae portion) Standing or sitting Attempts are made to carry the shoulder backward against resistance The lower part of the muscle can be felt and often seen Nerve supply C_3, C_4

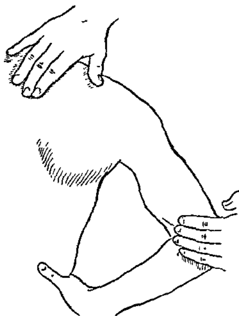

Fig 6-22 Rhomboideus muscles Patient standing, elbow flexed and extending laterally with hand on hip tries against resistance to brace shoulder backward The muscle can be seen and felt Nerve supply C_4, C_5

The painful lesions of the shoulder due to a slowly developing internal derangement, some of which are associated with trauma, others not, are (1) frozen shoulder, capsulitis, tendinitis, peritendinitis or periarthritis, (2) calcified subdeltoid bursitis or degeneration of the supraspinatus tendon and (3) tears of the supraspinatus tendon and of the musculotendinous cuff. Regarding these painful shoulders certain facts as enumerated by Ghormley have come to be accepted. 1. The supraspinatus tendon tends to degenerate and the frequency of this occurrence increases with age. 2. There is general agreement that the so-called *periarthritis* or *frozen* shoulder has its inception in inflammation of the tendon or tendon sheath 3 Calcification in bursae probably results from accumulation of degenerated tendinous material. 4. Ruptures of the supraspinatus tendon are fairly common in older persons. They may cause severe symptoms in some cases and require surgical treatment. 5. Among younger persons, subsequent to trauma, tears of the musculotendinous cuff are much more severe and serious than among older persons

In addition to these facts enumerated by Ghormley, Bickel has enumerated

with hypesthesia, paresthesia or anesthesia In time atrophy of the muscles of the hands supervenes. If the pressure and circulatory insufficiency are allowed to continue, pressure on the subclavian artery decreases the volume of the radial pulse. Peripheral thrombosis may occur and may be so extensive that gangrene ensues.

EXAMINATION. Palpation of the supraclavicular fossa is made in an attempt to detect a *cervical rib or any difference in the prominence of the structures in the* fossa and tenderness on pressure over the scalenus anticus muscle Pressure over this muscle causes extension of the pain down the ulnar side of the arm.

The two radial pulses are examined for evidence of differences in the volumes While palpating the radial pulse, request the patient to turn the head upward toward the affected side, to inspire and to hold the breath. If there is abnormal pressure by the scalenus anticus muscle on the artery, the pulse volume will be decreased or the pulse may be obliterated and the symptoms will be reproduced.

DIAGNOSIS. The diagnosis of the scalenus anticus syndrome is based on the presence of pain, atrophy, circulatory abnormalities and disturbance of sensation in the *upper extremity. The presence of cervical ribs is not sufficient evidence to warrant* a diagnosis of the scalenus anticus syndrome since, as stated, cervical ribs usually do not present symptoms

DIFFERENTIAL DIAGNOSIS The differential diagnosis of scalenus anticus syndrome requires a consideration of the following: (1) brachial neuritis; (2) Raynaud's disease, (3) thromboangiitis obliterans (Buerger's disease); (4) subacromial bursitis; (5) protrusion of a cervical intervertebral disk, and neoplasms of the cervical portion of the spinal cord, and (6) cervical spondylitis

THE AXILLA

Have the patient raise the arm directly out from the body. The armpit and axillary folds are thus made visible

The axilla is a wedge-shaped space with its apex upward, formed between the arm and chest at their junction It serves as a passage for the arteries, veins, nerves and lymphatics between the trunk and the upper extremity It is frequently the site of growths and abscesses

The rounded edge of the anterior axillary fold is formed by the pectoralis major muscle. It follows the fifth rib, and its upper end merges with the lower edge of the deltoid muscle The posterior fold is formed by the latissimus dorsi and teres major muscles By deep upward pressure with the extended approximated fingers in the axilla, the rounded head of the humerus can be felt.

Lymphatic structures of the axilla, especially the axillary lymph nodes, combined with a few scattered nodes in the antebrachium and the brachial regions, drain the entire upper extremity The axillary nodes receive the afferent vessels from the anterior and the lateral aspects of the thoracic wall, from the breast, and posteriorly from the scapular region These axillary nodes are anatomically situated in two groups, the axillary nodes proper and the subclavian nodes

The lymphatics of the middle and lower portions of the back as low down as the umbilicus also drain into the axilla

These lymph nodes communicate with one another The part affected ordinarily drains to the nearest nodes Occasionally, however, the infection may pass by or through one set of nodes without causing enlargements and may involve a neighboring communi- [illegible] or scapular [illegible]

[illegible] are always palpable When they are not enlarged, they cannot all be found. The size of the normal lymph nodes is usually inversely proportional to the number of nodes present In an axilla in which there are few nodes some of these may be palpable normally

The subclavian nodes lie in the infraclavicular triangle between the pectoralis major

fibromas or inflammatory lesions as well as malignant lesions may cause it. Pain from lesions of the esophagus is rarely referred to the arm. Diaphragmatic lesions, however, may cause pain in the arm. This is particularly true of lesions of the central portion of the diaphragm, such as esophageal hiatal hernias. Diaphragmatic pleurisy or irritation also may cause pain in the shoulder and arm.

Ankylosis of the Shoulder. The relative loss of co-ordination, endurance and security in respect to the duties of the arm and hand will vary according to the extent the ankylosis approaches or departs from the more favorable position of about 50 to 60 degrees abduction (McBride).

Partial Ankylosis. Partial limitation of motion in the shoulder is often due to a periarticular derangement of tissues resulting from trauma such as contusion and fractures of the head or surgical neck of the humerus A sprain or dislocation may leave permanent damage to the capsule and ligaments of the joint. Habitual dislocation is not commonly associated with a painful or stiffened joint The supraspinatus muscle or tendon may be ruptured, and if so the rupture is difficult to recognize

Continuous immobilization with the arm to the side will result in permanent contraction of the adductors and atrophy of the deltoid, so that there is no power to lift the arm outward Paralysis of the deltoid may follow a fall directly on the shoulder which injures the circumflex nerve Such a paralysis may be permanent

Suppuration and persistent sinuses may exist for many months after a compound fracture of the shoulder Movement of the joint will be greatly hampered Osteomyelitis may follow a compound fracture and may cause permanent disability Adhesions from this source do not respond well to manipulation

A rheumatic fibrositis may complicate injury to the shoulder. When it does, the pain is persistent and improvement is slow A deltoid bursitis may occur spontaneously or be induced by injury There may be a tenosynovitis of the long head of the biceps to add more to the pain and disability

When the scapulohumeral joint is ankylosed, shoulder joint action is completely lost if there is no movement of the scapula Ankylosis is incomplete if the scapula is free With fixation of the arm at the side there is complete loss of motion. The hand can perform its functions in the sagittal plane only by means of the forearm, and the center of action is now situated at the waist instead of in the shoulder.

When the scapula is free, there is considerable freedom of motion rendered through the gliding of the scapula and through the sternoclavicular joint. The amount of motion afforded through the scapula greatly lessens the severity of rigid ankylosis in the scapulohumeral joint.

When fixation of the shoulder joint occurs with the arm more than one half abducted and slightly flexed with rotation at midpronation, it is in a useful position. This position permits more flexibility at the shoulder while lifting than other positions permit. When the scapula is fixed, the disability is much more severe than when it is free.

The Scalenus Anticus Syndrome With and Without Cervical Rib. The scalenus anticus syndrome may be associated with a cervical rib or it may occur spontaneously The symptoms are attributable to irritation and compression of the [illegible]

produce symptoms. These ribs occur unilaterally or bilaterally and [illegible] length.

SYMPTOMS The commonest and often the first symptom is a sharp pain originating from a sudden rotation of the head or from a forceful downward pull of the shoulder. In the intervals between these sharp pains there may be a dull, aching, burning and boring pain occurring during the latter part of the day or with fatigue. The pain extends the length of the inner side of the arm and may be associated

Projecting on each side of the elbow are the two epicondyles of the humerus These bony projections do not belong to the forearm. The two epicondyles are nearly on the same level. The medial (internal) is the more prominent. By deep pressure the lateral (external) supracondylar ridge can be felt running up the arm somewhat posteriorly from the lateral (external) epicondyle. The medial (internal) supracondylar ridge is much less easily felt. When the elbow is flexed at a right angle, a plane parallel with the humerus passes through the two epicondyles and the tip of the olecranon. If the forearm is extended, the olecranon passes somewhat in front of this plane. Hence in examining the elbow for injury it is desirable to determine the relation of these points when the elbow is bent at a right angle.

The elbow is now examined while the arm is extended. In this position the tip of the olecranon can be felt with the medial (inner) epicondyle to its inner side. Between the medial and lateral epicondyles is a deep groove and in this groove can be felt the head of the radius.

On the posterior aspect of the elbow joint is the ulnar nerve. A bursa lies between the upper or posterior surface of the olecranon and the skin; and also another on its inferior surface, extending downward, which from its exposed position is frequently injured and enlarged Such an enlargement occurs from chronic irritation in certain occupations (as mining), hence the name miner's elbow

In the middle of the flexor surface of the elbow below the crease is a depression called the antecubital fossa. To its outer side is the muscular prominence of the extensors and supinator. To its inner side is the muscular prominence of the flexors and pronator The inner muscular swell ends at the medial (internal) condyle, but the external one passes well up on the arm.

The *antecubital fossa* or space is occupied by a number of *veins* which are of importance because they are frequently used for purposes of parenteral medication, sometimes for blood transfusions, and not infrequently they are wounded and give rise to hemorrhage.

The Elbow and Monarticular Disorders. The diseases of the region of the elbow include inflammatory processes and neoplasms Inflammations of the elbow and its neighborhood may be acute or chronic. In *acute arthritis* the whole circumference of the joint is tender on pressure, the swelling being most marked where the capsule is most superficial

Chronic arthritis of the elbow joint may be due to rheumatoid arthritis, tuberculosis or syphilis. An arthritic involvement is not likely to be confused with simple chronic bursitis olecrani or with epicondylar neuralgia.

Of the *tumors* of the region of the elbow, those of intramuscular origin include angioma and sarcoma. The simple muscle hernia due to the bulging of contracted muscle through a defect in the aponeurosis of a muscle, following trauma or congenital defect, is easily distinguished from neoplasm. Similarly, calcification within a muscle following trauma, the so-called traumatic osteoma, in reality a circumscribed ossifying myositis, is differentiated from tumor by the history of trauma and by roentgenographic examination, the appearance in roentgenograms is distinctly characteristic.

Tumors originating in the nerves rather than in the muscles can be differentiated from muscle tumors by their position in the course of the nerves and by their spindle shape They consist usually of neurofibromas, more rarely of sarcomas.

Inflammations of the bones may be acute (osteomyelitis) or chronic (chronic staphylococcal osteomyelitis, sporotrichosis, tuberculosis or gumma). The neoplasms of the bones found in the region of the elbow are most often myeloid sarcomas; occasionally other forms of sarcoma, fibroma or enchondroma may be met with.

Ankylosis of the Elbow. The function of the elbow is to serve the hand and

and deltoid muscles and on the front of the subclavian vein above the pectoralis minor muscle. They receive radicles from the mammary gland as well as from the axillary groups. They receive the overflow either directly or indirectly from all the other lymphatics of the foregoing regions They may empty through the subclavian trunk into the subclavian vein near its junction with the external jugular vein or into the right jugular vein. These nodes may be palpable in the presence of carcinoma of the breast.

Axillary Tumors. Tumors of the axilla are almost always due to involvement of the lymph nodes They may be inflammatory, forming the ordinary axillary adenitis, they may be tuberculous, or they may be malignant. Since the tumors of the axilla are often due to disease of the lymph nodes, the parts which the nodes drain should be searched to determine *the starting point of the disorder.*

Chronic infections of the glands of the skin cause tender axillary indurations. Lipomas, accessory breasts or breast tissues may be present in the axilla, but more commonly these occur along its anterior margins.

THE ARM

The arm has four sets of muscles to perform its four directional movements These sets of muscles are (1) the lateral group (abductors), (2) the internal group (adductors), (3) the anterior group (flexors) and (4) the posterior group (extensors)

The deltoid forms the large rounded prominence of the shoulder. At its insertion the humerus is nearest the surface and easily palpable The posterior edge of the deltoid can be plainly seen, when contracted, running upward and inward and crossing the posterior fold of the axilla at right angles. Its anterior edge blends more or less completely with the pectoralis major

The *biceps brachii and the brachialis form the muscular mass on the anterior* surface of the arm. The *posterior* or extensor set of muscles includes the triceps

On the medial aspect in the lower third of the arm the brachial artery is covered only by the skin and superficial and deep fascia, and can be felt pulsating along the inner edge of the biceps muscle and tendon, it can be compressed against the bone by pressure directed outward At this point tourniquets may be applied

THE ELBOW JOINT

The elbow joint is a hinge joint The articulation between the trochlea and the ulna is so shaped as to allow no lateral motion, but only an anteroposterior one. The forearm can be extended to an angle of 180 degrees, or in a straight line with the arm It can be flexed to an angle of 30 to 40 degrees Sometimes it cannot be flexed so much, so that if after an injury to the joint the patient can flex the elbow to half a right angle, this may be regarded as the normal amount of motion

The axis of motion of the elbow joint (the radial aspect anteriorly) slopes slightly from the lateral side downward and inward. The effect of this slope is to give a slight obliquity to the motions of flexion and extension This obliquity is not noticeable except in extreme extension and flexion When the forearm is completely extended (palm forward) it is seen not to lie in the axis of the arm but to bend outward from the elbow at an angle of 170 degrees. This angle is called the *carrying angle* because, by resting the elbow against the side, any article which is carried in the hand, as a bucket of water, is kept away from the lateral aspect of the leg.

In *examining the elbow* it first should be flexed at approximately a right angle. The prominent olecranon process is the posterior projection of the elbow. It is subcutaneous, and it can be felt and followed down the back of the forearm. From the tip upward for a comparatively short distance can be felt the upper surface of the olecranon, into which the triceps inserts To feel this upper surface distinctly, *the forearm should* be somewhat extended to relax the triceps so that the outline of the upper portion of the olecranon is distinctly palpated

ample, the screw driver). These instruments are therefore designed for right-handed individuals. A left-handed individual's greatest handicap is that of having to use instruments which were not designed for him.

THE WRIST

There is a bony prominence on each side of the wrist caused by the expanded lower end of the radius on the side of the thumb (medial) and head of the ulna on the side of the little finger (lateral) The medial (inner) prominence is exemplified by abducting the hand, the lateral (outer) prominence of adducting it.

Proximal to the wrist on the anterior and medial part can be felt the sharp and prominent distal 1 inch (about 2.5 cm) of the radius Following the bone distally on its medial side, one feels the tip of the styloid process, a most important landmark The styloid process is in the anatomist's snuffbox (tabatière anatomique), a depression on the dorsal aspect of the wrist, just below the radius

Between the tip of the styloid process of the radius and its sharp anterior border are the extensor ossis metacarpi pollicis and extensor brevis pollicis tendons. The sheaths of these tendons frequently become inflamed from injuries. If the examining hand is placed firmly on the lower portion of the radius of a patient so affected, and the patient moves the thumb, a characteristic grating irregularity of movement of the tendons can be palpated as they move in their inflamed sheaths.

If the posterior surface of the ulna is followed downward, the styloid process forming its extremity can be distinctly felt, especially if the patient's hand is placed in the supine position and slightly flexed

The styloid process of the radius extends lower than that of the ulna Across the central (palmar) surface of the wrist there are two transverse lines The proximal or upper one corresponds to the wrist joint The distal or lower one corresponds to the joint between the two rows of carpal bones.

On the dorsal surface of the wrist when in pronation, one third of the width of the wrist across from the edge of the radius, can be felt a bony prominence. This prominence marks the middle of the posterior surface of the radius The radius occupies two thirds of the dorsal surface of the wrist, and the ulna the other third; by firm pressure the interval between the bones can be felt

The wrist joint has no movement of rotation Rotation of the hand is accomplished by pronation or supination of the forearm The hand can be flexed and extended through an arc of approximately 140 degrees, and adducted and abducted about 70 degrees. Adduction or bending toward the ulnar side is much greater than abduction or movement toward the radial side

The extent of the movements of the wrist varies individually.

Ankylosis of the Wrist. The function of the wrist is to serve the fingers and hand in carrying out such duties as reaching, pointing, grasping, pinching, holding, pushing, pulling, striking, carrying, swinging, throwing, turning and lifting The hand and fingers, in execution and achievement of their appointed functions, require the elbow and shoulder to serve their purposes

The causes of partial or complete ankylosis of the wrist are contusion or sprain, tenosynovitis or ganglion, fracture and dislocation, suppuration, continuous and prolonged immobilization, scar contraction and shortening of muscles, paralysis and rheumatic fibrositis

Partial Ankylosis. Sprains are often accompanied by prolonged disability and may result in permanent loss of function Effusion into the wrist joint often hampers the joint motion for long periods of time if not permanently. Sprains may be distinguished from tenosynovitis by the limitation of the swelling at the joint lines and do not extend up and down in the direction of the tendons In traumatic synovitis there is an aseptic effusion of blood and serum into the joint, and in case of the wrist joint there are so many pouches and cartilaginous reflections about the carpal

arm in carrying out the motions entailed by reaching, pointing, holding, pushing, pulling, striking, carrying, swinging, throwing, turning and lifting.

Ankylosis of the elbow joint may result from dislocations, contusions, suppurations, prolonged immobilization, scar contracture, myositis ossificans and rheumatic fibrosis.

Partial Ankylosis. When the range of elbow motion is less than a right angle, the arm, which is subservient to the hand, does not provide flexibility. Any motion at all is preferable to rigid fixation; motion from 90 degrees to 35 degrees flexion is useful in the lighter activities but such motion will not permit carrying, pulling or pushing heavy objects.

When the range of motion of the elbow joint is from 180 to 80 degrees, the greater portion of the requirements for accommodation of the hand and arm are fulfilled In the performance of the motions required for lifting, pushing, pulling or carrying, the angle approaching 120 degrees is more desirable than a right angle (McBride)

When the elbow joint action is lost, the arm is stiffened solidly. The stiffened arm and the hand have their fulcrum at the shoulder, and can perform only as far as the shoulder muscles are able to manipulate the entire arm The manual functions are greatly reduced because of inability to get the hand where it is needed.

THE FOREARM

Anteriorly the muscles and tendons can be palpated The extent to which these can be outlined by the examiner depends on the absence of subcutaneous fat and the degree of development and contraction of the individual muscles The skin of the forearm is loose and thin. The median vein is situated on the flat surface; the radial vein winds around the back of the wrist and crosses the outer edge of the radius about its middle On the medial side near the elbow the anterior and posterior ulnar veins are visible as they pass posteriorly

On the posterior surface of the forearm the bones are more conspicuous than on the anterior surface because they are subcutaneous By palpation the ulna can be traced down the forearm, running from the olecranon process down to its styloid process at the back of the wrist To the outer side of the olecranon can be felt the lateral (external) epicondyle and the capitulum humeri If the elbow is extended, a dimple is seen just below the capitulum humeri, it marks the position of the head of the radius.

By placing the thumb of one hand in the dimple on the head of the radius, and *rotating the hand of the patient with the other, the examiner can feel rotation* of the bone and thus be assured that the radius is intact Whenever fracture of the radius is suspected, this is the procedure resorted to in order to determine whether or not the radius is broken

The radius can be followed distally only for a distance of about 1 inch (about 2 5 cm.), where it disappears beneath the muscles to become subcutaneous again on the lateral side of the middle of the forearm. Thence it can be palpated to the styloid process on the lateral side of the wrist

Movements of the Forearm. In the midposition, with the radius above the ulna, the space between the bones is at its maximum. It is this space which, if encroached on by poor apposition of fractured bones, results in limitation of movements of pronation and supination The head of the radius rotates in the orbicular ligament; the lower end of the radius revolves around the head of the ulna The range of movement is from 140 degrees to 160 degrees.

The muscles of supination are stronger than those of pronation, and it is for this reason that *instruments intended* to be used in a rotary manner are *designed to turn* from the inside toward the outside, that is, in the direction of supination (for ex-

situated in the hand itself An especial accomplishment of the human hand is the ability to oppose the thumb to the other digits

Movements. The motion between the individual carpal bones is limited to a slight gliding on one another. The summation of these motions, however, permits considerable range of movements. These movements are flexion and extension, abduction and adduction and circumduction. If motion is prevented in the bones of the forearm, it is impossible to rotate the hand.

The *radiocarpal joint* has a greater degree of flexion than of extension The movement permitted between the two rows of carpal bones is extensive

The movements of the four midcarpometacarpal joints are flexion (toward the palmar surface) and slight extension There is slight lateral flexion and extension which enables cupping of the hand for grasping round objects. The articulation of the thumb allows flexion, extension, abduction, adduction, and circumduction, but not rotation.

The *metacarpophalangeal articulations* of the fingers are practically saddle-shaped joints resembling somewhat the ball and socket joints with all their movements except that of rotation They can be flexed to an angle of 90 degrees The interphalangeal joints are hinge joints and capable only of flexion and extension The second joint can be flexed to an angle of 120 degrees and the end joint to about a right angle The prominence of the knuckle is formed by metacarpal bone.

Functional Testing of Muscles of the Arm and Hand. *Biceps.* The patient extends the arm and flexes it at the elbow. Further attempts of flexion are resisted by the examiner The muscle can be seen and felt (Fig 6-24). (Musculocutaneous nerve supply, C_5, C_6)

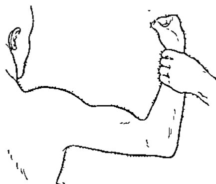

Fig. 6-24 Biceps muscle Standing or sitting with the arm extended laterally at the shoulder and supinated and flexed at the elbow Attempts are made to flex the supinated arm at the elbow The muscle can be seen and felt Nerve supply C_5, C_6 *(musculocutaneous nerve)*

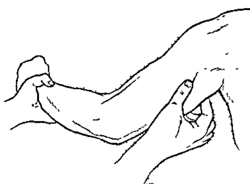

Fig 6-25. Triceps muscle Long heads Standing, sitting or lying so that the force of gravity is inoperative on the flexed arm at the elbow Attempts are made to extend the forearm against resistance The muscle can be seen and felt in either place shown Nerve supply C_7, C_8 *(radial nerve)*

Triceps The triceps may be tested as is the biceps, except that the previously flexed arm is to be extended against resistance. The muscle can be seen and felt The long heads of the triceps muscle can be palpated here (Fig 6-25) The whole or cross section of the triceps muscle can be palpated at the level of the arm indicated (Fig 6-26). (Radial nerve supply, C_7, C_8)

Brachioradialis. With the forearm midway between pronation and supination, the attempt at flexion renders the belly of the muscle evident (Fig 6-27). (Radial nerve supply, C_5, C_6)

Extensor Carpi Radialis Longus With the fingers extended, attempt is made to extend the wrist to the radial side The contracted muscle can be felt (Fig 6-28). (Radial nerve supply, C_6, C_7)

bones that adhesions from the coagula may become very extensive. Rheumatic fibrositis is recognized by persistent and painful stiffness. It is commoner in those past 40 years of age than in younger persons.

As the angle of extension is lost in the wrist, the flexion power of the fingers is diminished accordingly and the deformity becomes more disabling. The prominence of the base of the hand over which the flexor tendons pass increases the flexor tension as the hand is dorsiflexed. When the hand cannot be dorsiflexed to or past the 180 degree line, therefore, the long flexor tendons are at a disadvantage. Rigid fixation in flexion eliminates the action of all muscles of the wrist. The flexion power of the fingers is less when the fixed position is in abduction to the radial side than when in adduction to the ulnar side.

When the wrist is fixed in *dorsiflexion*, the palm of the hand is serviceable and the prominence of the base of the hand retains its function. The flexor action of the fingers approaches normal The degree of adduction decreases the strength of fingers, while abduction strengthens them. The thumb flexors are improved in strength in the position of ulnar flexion or adduction. In fixed ankylosis, therefore, midpronation is the position of choice.

When the limitation of rotation originates at the elbow, the biceps may be influenced through limitation of flexion.

In the ankylosed position of full supination the hand is turned the wrong way to be useful. As the range of motion approaches midway between pronation and supination, the fingers and hand increase in their usefulness but the most useful position is that of about 35 to 45 degrees of pronation (McBride)

THE HAND

Man alone has a hand All other mammals have paws or front feet With respect to length, the hand is classified as being long or midlong or short. With respect to breadth, the hand is spoken of as being broad, midbroad or narrow. Absolute breadth of the hand increases with age and is enhanced by physical labor in the early period of life, so that among middle-aged adults there are more than twice as many broad hands as all other widths combined

On the dorsum of the hand the extensor tendons can be seen Accessory slips usually connect the tendon of the ring finger with the tendons of the little finger and middle finger A slip also usually passes from the tendon of the middle finger to that of the index finger.

On the dorsum of the hand the metacarpal bones are subcutaneous and can be felt in their entire length The muscular prominence on the dorsum of the hand seen when the thumb and the forefinger are approximated is due to the abductor indicis muscle. At its upper extremity the radial artery passes between the two heads of the muscle to enter the palm When the thumb is extended, the *anatomist's snuffbox* becomes evident and the extensor pollicis longus tendon is distinctly seen leading to the ulnar side of the posterior radial (thecal) tubercle on the middle of the dorsum of the radius. The tendons on the radial side of the snuffbox are the extensor brevis and extensor ossis metacarpi pollicis.

If the hand is turned with the palm up, the thumb diverges from the median line at varying angles The palm is the hollow of the hand formed by a muscular mass on each side. On the thumb side is the *thenar eminence*, on the ulnar side is the *hypothenar eminence* The palm is marked by four creases, two longitudinal and two transverse, caused by flexions of the digits. Fortunetellers lay more stress on their "knowledge" of the importance of these creases than they deserve.

The fingers perform many complicated movements. The movements of the hand and fingers are accomplished by the action of the long flexors and extensor muscles of the fingers and the flexor and extensor muscles of the carpus, which arise in the forearm. Perfection of motion is added by the actions of numerous short muscles

Abductor Pollicis Longus. The patient tries to abduct the thumb in a plane at right angles to the palm. The tendon can be seen and felt (Fig. 6-32). (Radial nerve supply, C_7-C_8.)

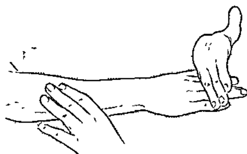

Fig 6-30 Extensor digitorum muscles. Forearm and hand resting on flat surface with the palm downward Attempts are made to flex the fingers against resistance Nerve supply C_7, C_8 (radial nerve)

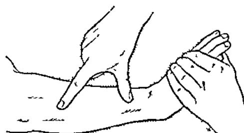

Fig. 6-31 Extensor carpi ulnaris muscle Flexor surface of the arm down on flat surface Attempts are made to extend the wrist joint to the ulnar side against resistance Nerve supply C_7, C_8 (radial nerve).

Extensor Pollicis Brevis. The patient resists an attempt to flex the thumb at the metacarpophalangeal joint The tendon can be seen and felt (Fig 6-33). (Radial nerve supply, C_7-C_8)

Extensor Pollicis Longus The patient resists an attempt to flex the thumb at the interphalangeal joint The tendon can be seen and felt (Fig 6-34). (Radial nerve supply, C_7-C_8)

Pronator Teres The patient extends the arm by the side and resists the examiner's attempt to supinate the hand The muscle belly can be felt and sometimes seen (Fig 6-35) (Median nerve supply, C_6-C_7.)

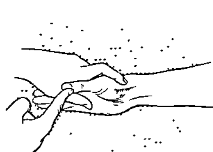

Fig 6-32 Abductor pollicis longus muscle Ulnar surface of arm flat on table Attempts are made to abduct the thumb in a plane at right angles to the palm The tendon can be felt and seen Nerve supply C_7, C_8 (radial nerve)

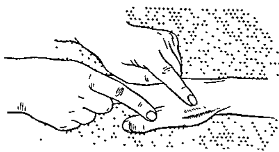

Fig 6-33 Extensor poll . . . [illegible] seen and felt Nerve supply C_7, C_8 (radial nerve)

Flexor Carpi Radialis The patient tries to flex the wrist toward the radial side against resistance The muscle belly can be felt and the tendon can be seen (Fig 6-36) (Median nerve supply, C_6, C_7, C_8)

Flexor Digitorum Sublimis. The patient resists an attempt to straighten any finger at first interphalangeal joint, while the proximal phalanx is fixed The con-

Supinator Brevis. The patient extends the arm by the side, and resists the examiner's attempt to pronate the hand (Fig. 6-29). (Radial nerve supply, C_5, C_6.)

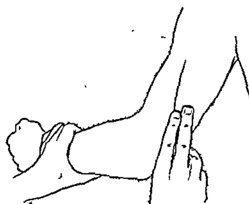

Fig 6-26 Triceps muscle The long heads or a cross section of the whole muscle can be palpated here when the patient tries to extend the arm against resistance (nerve supply C_7, C_8)

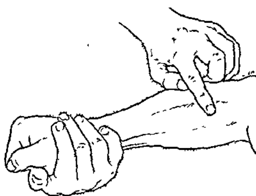

Fig 6-27 Brachioradialis muscle Arm flexed at the elbow while patient stands or sits The forearm midway between pronation and supination Nerve supply C_5, C_6 (radial nerve)

Extensor Digitorum Communis The patient resists an attempt to flex the fingers at the metacarpophalangeal joints. The muscle belly can be felt and sometimes seen (Fig 6-30). (Radial nerve supply, C_7, C_8)

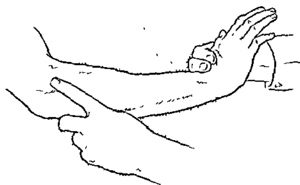

Fig. 6-28 Extensor carpi radialis longus Flexor surface of arm downward on flat surface Attempts are made to extend the wrist to the radial side against resistance The muscle can be felt Nerve supply C_6, C_7 (radial nerve).

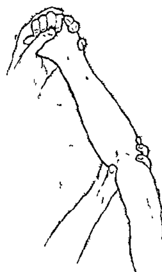

Fig 6-29 Supinator muscle Standing, lying or sitting with arm extended by the side Attempts are made to prevent the hand from being forcibly pronated Nerve supply C_5, C_6 (radial nerve)

Extensor Carpi Ulnaris. The patient tries to extend the wrist joint to the ulnar side against resistance The muscle belly can be felt and the tendon can be seen and felt (Fig 6-31). (Radial nerve supply, C_7-C_8)

Flexor Pollicis Longus The patient resists an attempt to extend the terminal phalanx of the thumb, while the proximal phalanx is fixed (Fig. 6-39). (Median nerve supply, C_8-T_1.)

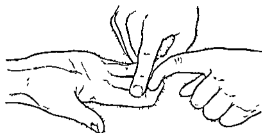

Fig 6-38 Flexor digitorum profundus muscle, I and II. Hand on firm surface, palm upward, the second phalanx is held in place, and attempts are made to extend the terminal phalanx of the index finger against resistance while the middle finger is fixed Nerve supply C_8, T_1 (median nerve)

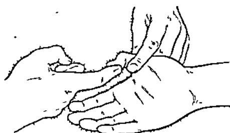

Fig 6-39 Flexor pollicis longus muscle Hand on firm surface, palm upward, the proximal phalanx is held by the examiner. Attempts are made to extend the terminal phalanx of the thumb against resistance while the proximal phalanx is fixed Nerve supply C_8, T_1 (median nerve).

Abductor Pollicis Brevis. The patient's thumb is placed so that the nail is in a plane at right angles to the palm of the hand, while supporting an object such as a pencil between the thumb and palm. The patient then tries against resistance to bring the edge of the thumb to a point vertically above its original position The thumb nail maintains its position in a plane at right angles to the palm (Fig 6-40). (Median nerve supply, C_8-T_1)

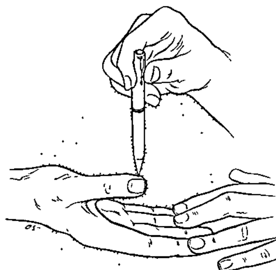

Fig 6-40 Abductor pollicis brevis muscle Hand on flat surface, palm upward, end of thumb over proximal palmar surface of index finger Attempts are made against resistance to bring the thumb to a position vertically above but proximal to the starting point while the thumbnail maintains its position in a plane at right angles to the palm Nerve supply C_8, T_1 (median nerve)

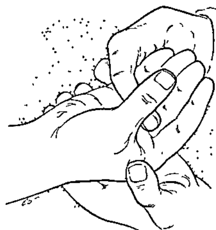

Fig 6-41 Opponens pollicis muscle The patient's arm at the elbow rests on firm surface with palm upward Attempts are made against resistance to touch the tip of the little finger with the thumb while the thumbnail remains parallel to plane of the palm The contraction of muscle is manifested by pressure exerted on examiner's right index finger. Nerve supply C_8, T_1 (median nerve).

vincing sign is the ability to flex the proximal joint while the terminal joint remains flaccid (Fig. 6-37). (Median nerve supply, C_7, C_8, T_1.)

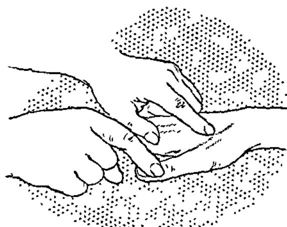

Fig 6-34. Extensor pollicis longus muscle Palmar surface of hand on flat firm surface Attempts to flex the thumb at the interphalangeal joint are resisted (Tendon can be seen and felt) Nerve supply C_7, C_8 (radial nerve)

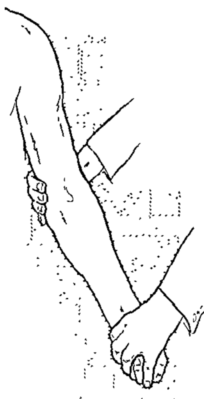

Fig 6-35 Pronator teres muscle Standing, sitting or lying with arm extended by side Attempts to supinate the hand are resisted The muscle can be felt Nerve supply C_6, C_7 (median nerve)

Flexor Digitorum Profundus I and II. The patient resists an attempt to extend the terminal phalanx of the index finger, while the second phalanx is fixed (Fig. 6-38) (Median nerve supply, C_8-T_1)

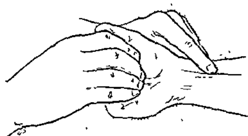

Fig 6-36 Flexor carpi radialis muscle Attempts are made to flex the wrist toward the radial side The muscle can be felt and seen. Nerve supply C_6, C_7, C_8 (median nerve).

Fig 6-37 Flexor digitorum sublimis muscle Hand on firm surface with palm upward, the proximal phalanx is fixed by pressure from the examiner's fingers. Attempts are made to straighten any finger at its first interphalangeal joint The proximal joint can be flexed while the distal joint remains flaccid. Nerve supply C_7, C_8, T_1 (median nerve).

flexor carpi ulnaris is intact, this movement is observed even when abductor digiti minimi is paralyzed. (Ulnar nerve supply, C_7-C_8.)

Flexor Digitorum Profundus III and IV. The patient resists an attempt to extend each finger in turn at the distal interphalangeal joint, while the middle phalanx is fixed (Fig. 6-45). (Ulnar nerve supply, C_8-T_1.)

Abductor Digiti Minimi. With the back of the hand and the fingers flat upon a table, the patient tries against resistance to abduct the little finger. The muscle belly can be felt (Fig. 6-46). (Ulnar nerve supply, C_8-T_1.)

First Dorsal Interosseous Muscle. With the fingers and palm flat upon a table, the patient tries against resistance to abduct the index finger. The muscle belly can be felt and usually seen (Fig. 6-47). (Ulnar nerve supply, C_8-T_1.)

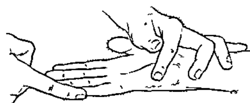

Fig. 6-46 Abductor digiti minimi muscle. Hand on firm surface, palm upward and held in place by the examiner. Attempts are made against resistance to abduct the little finger. The muscle can be seen and felt. Nerve supply C_8, T_1 (ulnar nerve).

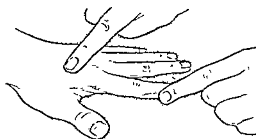

Fig. 6-47 First dorsal interosseous muscle. Hand on firm surface, palm downward and snugly applied. Attempts are made to abduct index finger against resistance. Nerve supply C_8, T_1 (ulnar nerve).

First Palmar Interosseous Muscle. With the fingers and palm flat upon a table, the patient tries against resistance to bring the abducted index finger toward the median line (Fig. 6-48). (Ulnar nerve supply, C_8-T_1.)

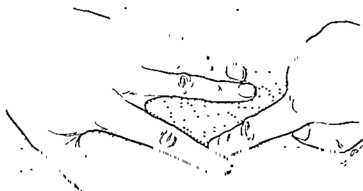

Fig. 6-48 First palmar interosseous muscle. Hand on firm surface, palm downward and snugly applied to the surface. Attempts are made against resistance to bring the abducted index finger back in place. Nerve supply C_8, T_1 (ulnar nerve).

Adductor Pollicis. With the thumb placed along the palmar aspect of the index finger, the patient tries against resistance to retain a piece of paper between the thumb and the palm (Fig. 6-49). (Ulnar nerve supply, C_8-T_1.)

Opponens Pollicis. The patient tries against resistance to touch the tip of the little finger with the thumb, while the thumb nail remains in a plane parallel to the palm (Fig. 6-41). (Median nerve supply, C_8-T_1.)

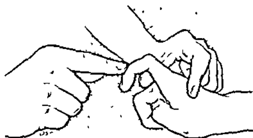

Fig. 6-42 Lumbrical-interosseous muscle of index finger Arm with palmar surface downward on firm base, hand held by examiner while the first metacarpophalangeal joint is hyperextended and fixed Attempts are made to extend the first interphalangeal joint against resistance The muscle can be seen and felt Nerve supply C_8, T_1 (both median and ulnar nerves)

Fig 6-43 Flexor carpi ulnaris muscle Hand with fingers extended, palmar surface *upward, on flat firm surface* Examiner's hand in place indicating extent of muscle Nerve supply C_7, C_8 (ulnar nerve)

Lumbrical-Interosseous Muscle (Index Finger). With the metacarpophalangeal joint hyperextended and fixed, the patient tries to extend the first interphalangeal joint against resistance. The belly of the first dorsal interosseous muscle can be seen and felt (Fig. 6-42). (Median and ulnar nerves, C_8-T_1.)

Fig. 6-44 Flexor carpi ulnaris muscle (little finger) Hand resting and fixed on firm surface, palmar surface upward, fingers extended Attempts are made to abduct the little finger The tendon can be seen and felt Nerve supply C_7, C_8 *(ulnar nerve).*

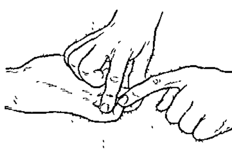

Fig 6-45 Flexor digitorum profundus III and IV of fingers Both fingers are tested as illustrated for little finger, While the middle phalanx is fixed on a firm flat surface attempts are made against resistance to extend the finger at the distal interphalangeal joint while its middle phalanx is fixed The strength of the flexors can be determined by the examiner's fingers Nerve supply C_8, T_1 (ulnar nerve).

Flexor Carpi Ulnaris. The patient lays the hand palm upward on the table, the fingers being extended (Fig 6-43). The patient then tries to abduct *the little finger* fully (Fig 6-44). The tendon of flexor carpi ulnaris can be seen and *felt* as the muscle comes into action to fix the point of origin of abductor digiti minimi. When

reddened. The uniformly reddened skin is the characteristic appearance. In mild cases only the eminences of the palms and fingers are affected. The color blanches on pressure with a more rapid return of the color than in the normal hand Fading of the color does not take place on elevation Definite flushing synchronous with pulse is observed when the color is partially obliterated with a glass slide.

On direct microscopic examination the capillaries are said to be more numerous and dilated than normally. Palmar erythema is often associated with vascular spiders.

Handedness and Its Associations. Handedness may be defined as the preferential use of either hand Most persons are right-handed A few are left-handed, and some have preferences for use of the hands which are different for different tasks

There seem to be varying degrees of left-handedness, but only an extremely left-handed person differs so greatly in motor activity from right-handed persons in a right-handed environment that he is set apart and is immediately recognized as such. The left-handed person is compelled to adapt and to adjust himself to a right-handed environment In most instances the process of adjustment and adaptation is so successful that not even the affected person is conscious of a left-sided tendency Consequently, special tests must be used in order to recognize this peculiarity with certainty Card shuffling is a very good test for evidences of handedness

Generally, total left-handedness must be regarded as exceptional It is observed, however, that this small percentage of left-handed or exceptional persons have more than their share of speech disturbances (see Stuttering, Chapter 15), epilepsy, and moral and physical defects

There are differences in the right and left sides of the body incident to or associated with handedness The right and the left halves of the face differ from each other and present varying degrees of asymmetry Wolff concluded that the right half of the face bears the individual expression which the person exhibits in daily life, it presents those character traits and features which the person desires to portray In contrast to this, the left half of the face bears the person's extra expression, representing the hidden character traits which arise in the subconscious The right half of the face in right-handed persons is directed by the left hemisphere, which represents the seat of all rational conscious processes. The right cerebral hemisphere, about the importance of which very little is known, controls the left half of the face, the half which bears the expression of the subconscious

In the absence of any means of orientation both men and animals move in circular paths *This trait of circumambulation is termed the turning tendency.* The turning tendency in humans is associated with handedness Right-handed persons turn chiefly toward the right, and left-handed ones to the left. This trait becomes apparent when a right-handed and a left-handed person are together and are lost in the woods The right-hander wishes to go to the right and the left-hander to the left and thus an argument ensues

The natural turning tendency in either man or animal is lost when the individual is wounded The path, after the person or animal is wounded—shot—is straight away from the scene of the tragedy

Regarding the postural and motor acts which are peculiar to man and which consist in interaction of two extremities, some individuals will favor one side and others will reveal no preference for either side, and thus these acts cannot be associated with handedness However, the manner in which a person folds the hands and crosses the arms rather specifically indicates handedness. For example, the superposition of the left thumb upon the right when the hands are folded is an indication of left-handedness

The foot which is passed forward to test the strength of ice or the softness of the ground before treading on it is an indication of footedness It may be observed that the footedness is contralateral to the handedness. For instance, a right-handed

Opponens Digiti Minimi. Fingers extended, the patient tries to make a cup of the palm and to carry the fifth finger in front of the others (Fig. 6-50). (Ulnar nerve supply, C_8-T_1) *

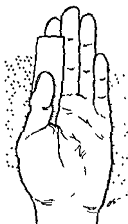

Fig 6-49 Abductor pollicis muscle Hand on firm surface, palm upward, fingers extended, thumbnail in a plane at right angles to the palm Ability to hold a piece of paper against resistance indicates intact muscle. Nerve supply C_8, T_1 (ulnar nerve)

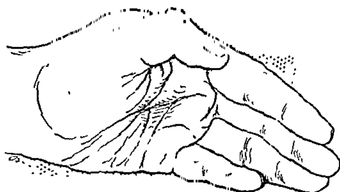

Fig 6-50 Opponens digiti minimi muscle The ulnar aspect of the arm rests on flat surface with thumb upward Attempts are made to form a cup of the palm while carrying the little finger in front of the others Nerve supply C_8, T_1 (ulnar nerve)

The Palmar Fascia. The palmar fascia or aponeurosis is the deep fascia of the hand It consists of a thick triangular middle portion and two thin lateral portions which cover the thenar and hypothenar eminences. This fascia is often involved in injuries and infections of the hand Dupuytren's contracture is a congenital anomaly involving the fascia of the hand (see Disease of Fascia, p 273).

Palmar Erythema. The palmar surface of the hand is less pigmented than is the dorsal surface. In the absence of callus, the lividity of the palmar and dorsal surfaces of the hand is equal A morbid redness of the skin of the palmar surface is palmar erythema, a condition due to dilatation of the capillaries in the pads of the palm and fingers The covering skin is normal

Palmar erythema on rare occasions may be present in an otherwise normal person. It is usually associated with some sort of chronic illness and often an illness in which there is an associated hypoalbuminemia. It may be present in liver disease and during the last trimester of pregnancy. However, it may be associated with chronic diseases of many kinds

Palmar erythema occurs in both men and women There are no symptoms. However, the patient may be concerned about the appearance of the hands.

Examination reveals symmetrically reddened eminences of the pads of the terminal digits, the palms and sometimes the soles of the feet. The transverse creases of the fingers may be of a deeper color than the adjacent skin The redness may extend over the finger tips to the nail beds and laterally over the distal phalanges. The color may be a diffusely mottled redness, small telangiectatic spots or uniformly

* Acknowledgment is made to the Controller of Her Britannic Majesty's Stationery Office for permission to make line drawings of photographs of muscles in action in War Memorandum No 7, reprinted 1945.

Of the *chronic inflammations* in and about the *wrist*, chronic infectious arthritis is very common. If one wrist alone is affected, and no other joints in the body are involved, tuberculosis of the joint is probable. It is easily distinguishable from tuberculous tenosynovitis, since in the latter the swelling is only on one side of the wrist, usually the volar side, and is most marked, not at the level of the wrist itself, but proximal and distal therefrom. The fingers are slightly flexed and there is no volar subluxation of the hand as in tuberculous arthritis

Of the chronic inflammations of the *hand* and *fingers*, the common ones are (1) tuberculosis of the tendon sheaths, especially of the flexor tendons, (2) gonorrheal tenosynovitis, (3) the stenosing tenosynovitis (radiating pain in the thumb and forearm on use), due to stenosis of the compartment of the tendon sheath for the extensor hallucis brevis muscle and the abductor hallucis longus muscle over the styloid process of the radius and (4) the spindle-shaped swellings of the metacarpal bones or phalanges, due to tuberculosis or to syphilis

Tenosynovitis (*Perimyotendinitis*). Traumatic tenosynovitis is distinct from pyogenic or granulomatous involvement of the tendon sheaths. The term tenosynovitis applied to the usual crepitating condition found proximal to the wrist joint is a misnomer The actual site of the lesion is well above the upper limit of the tendon sheaths at the wrist.

The local manifestations suggest that the lesion is essentially a perimyotendinitis involving the more proximal musculotendinous junction in the forearm It affects mostly factory workers, agricultural workers and housewives The tendons most frequently affected are the radial extensors of the wrist (extensor carpi radialis longus and brevis) and the abductor pollicis longus or extensor pollicis brevis, either alone or in combination The main factors in the etiology are unaccustomed movement, resumption of work after absence, repetitive stereotyped movement and local strain The prognosis is good, and cessation of work is neither desirable nor necessary.

Neoplasms. The wrists are rarely affected by neoplasms. The commonest tumors of the wrist are the osteophytic outgrowths from the bases of the distal phalanges in certain elderly persons The wrist joint may be affected by sarcoid and giant cell tumors

Diseases Due to Trauma or Physical Agent. ***Abscesses of the Hand and Fingers.*** Purulent collections in the palm of the hand either are situated beneath the palmar fascia or are connected with the sheaths of the flexor tendons

When pus collects beneath the palmar fascia, it is limited in the directions in which it can spread Pus originating beneath the thick middle triangular portion of the fascia may point in one or more of several places (1) on the inner side at the hypothenar eminence, (2) in the web of the thumb, (3) on the anterior surface of the forearm above the wrist and (4) on the webs of the fingers. Also in rare instances (5) it may burrow between the distal extremities of the metacarpal bones and show on the back of the hand and (6) if there should be, as is sometimes the case, tiny gaps in the fascia, a small amount of pus may accumulate above the palmar fascia and between it and the skin, so that there is a collection of pus both above and below the fascia

If the sheaths of the tendons of the hand or fingers become infected, the pus passes along the tendon as far as the sheath extends Since the extent of the tendon sheaths varies, it is well to recall that when suppuration occurs in the sheath of the thumb or little finger it is much more serious than in the other three, because the pus tends to pass directly upward, involve the palm and extend to the arm When suppuration involves the index, middle or ring finger, it stops when it reaches the vicinity of the metacarpophalangeal joints and involves the palm only. It may penetrate the carpal bursa

When the end phalanx becomes infected, the affection is known as a *felon* The

person may twist and prefer use of the left foot for purposes of exploration of the safety of the terrain for walking but will kick a football with the right foot.

Abnormalities of the Hand. The *spade hand*, large, coarse, thick-fingered, with broad nails, is seen as an evidence of myxedema, in which the enlargement affects mainly the soft parts; and in acromegaly, in which the enlargement affects the bones

The *clawhand*, also called *main en griffe* (griffin hand), is a deformity which occurs in consequence of paralysis and atrophy of the interossei and lumbricales muscles Paralysis of these muscles leads to a dorsal extension of the proximal phalanges with flexion of the others, and when atrophy takes place, the clawhand results. This abnormality suggests the existence of a neuritis of the median and ulnar nerves, particularly the latter, or progressive muscular atrophy. Similar deformities may be due to amyotrophic lateral sclerosis (the spastic form of progressive muscular atrophy), syringomyelia and, very rarely, the adult type of chronic anterior poliomyelitis

Atrophy of the muscles of the hand and forearm occurs in brachial palsies, but also to a slighter degree in cerebral paralysis in consequence of disuse and lower motor neuron lesions

Coldness of the hands and feet, with or without a tendency to sweating, if persisting for weeks or months, is most commonly due to neurasthenic conditions. Sudden or transient coldness of the extremities is observed in many persons, especially those of a nervous temperament, under excitement or anxiety, as well as in shock, collapse, hemorrhages and premonitory chilliness of rising fever. Coldness of the hands is also observed in Raynaud's disease and Buerger's disease It is necessary to discriminate between actual lowering of the temperature palpable to the observer and a subjective sensation of coldness The latter is a paresthesia

Excessive *sweating of the hands* may be due to nervous tension, toxic goiter and, occasionally, progressive muscular atrophy

In determining the existence of enlarged joints, it must not be forgotten that atrophy or wasting of the soft parts may cause an apparent increase in the size of the joints

Diseases of the Wrist and Hand. The more distinctly medical diseases of the wrist and hand include the inflammations, the neoplasms and trauma

Inflammations of the Wrist and Carpal Region. The *acute inflammations* of the wrist joint and its neighborhood (chirarthritis) are (1) acute arthritis of the wrist due to acute rheumatic fever or other forms of acute infectious arthritis and (2) acute inflammation of the vaginae mucosae (tenosynovitis) secondary to a penetrating wound of a finger, to a bite (human or animal) or other injury, or, sometimes, to metastatic infection

In tenosynovitis it is chiefly the movement of the fingers that is disturbed, whereas in arthritis of the wrist it is chiefly movements of the hand as a whole that are concerned, moreover, in arthritis there is everywhere about the affected joint tenderness on pressure, while in tenosynovitis only the side affected is tender Again, traction or compression in the long axis of the extremity is painful in arthritis, not in tenosynovitis. Extension of the inflammatory process in the longitudinal direction is characteristic of tenosynovitis, in arthritis, the inflammation remains limited to the joint region Sometimes, of course, arthritis and tenosynovitis occur together.

A painful swelling in the region of the long extensor of the thumb, accompanied by crackling on palpation over the tendon and muscle, is the so-called tenosynovitis crepitans; it is a chronic inflammation of the vaginae mucosae of the tendon and of the surrounding tissues

[illegible] The proximal [illegible] onic infectious

Eczema of the Hands. Eczema of the hands may be self-limited, as in occupational eczema of the hands in which the skin becomes hardened, or it may be a permanent state in which remissions and exacerbations alternate. A familial history of eczema or a history of infantile eczema is significant, because it indicates an allergic state.

There are many known causes for eczema of the hands and probably just as many unknown causes The known causes are fungous infections and their reactions, occupational irritants, dietary factors, neurodermatitis, dyshidrosis (pompholyx) and drug eruptions. The presence of an acute vesicular eruption indicates that the skin is hypersensitized and is prone to react unfavorably to therapeutic agents that are not mild and soothing

Eczema or dermatitis of the hands consists of a vesicular or scaling, oozing or weeping, crusted or infected eruption of the hands In the acute phase it is characterized primarily by vesicles and erythema, when subacute, by scaling and erythema, and in the chronic phase, by thickening or lichenification and scaling.

Diseases of the Nails. ***Congenital Abnormalities.*** Congenital absence of the nails (anonychia) is very rare It may be associated with congenital ichthyosis; if so, nails may or may not appear later in life

The presence of extremely small, otherwise apparently normal, nails is termed micronychia Extremely large nails (macronychia) appear as a congenital abnormality; they also develop later in life in the course of acromegaly or macrodactylia and may, at times, be associated with clubbing of the fingers

Pachyonychia is a congenitally thickened and discolored nail which may also be abnormally hard and longitudinally striated

Nails may be present in abnormal situations, for instance, on the palmar surface of a finger or the plantar surface of a toe This condition is known as onychoheterotopia.

Infections. Tuberculosis, anthrax, leprosy, virus of verruca vulgaris, syphilis, and mites of scabies may cause nail changes Most cases of suppurative paronychia, however, are caused by staphylococci, whereas nonsuppurative paronychia often results from moniliasis

Syphilis affects the nails in a variety of ways. However, these changes are not constant or definite. The diagnosis of syphilis is made on the presence of positive serologic reactions which are associated with other evidence of syphilis elsewhere in the body. If all of these findings are present and there is no evidence for any other causative disease, the changes in the nails may be attributed to syphilis

Fungous disease or "ringworm" of the nails—onychomycosis—causes severe disturbances of nail growth and local destruction of the nails of the toes or fingers Nail foci may provide sources of infection or reinfection to the glabrous skin The abnormalities of nail structure may be so severe as to be incapacitating, as in mycotic onychauxis and onychogryposis

The fungi causing the different types of onychomycosis are many and varied: Trichophyton, Epidermophyton, *Candida albicans* (*monilia*), Penicillium, Aspergillus (see Diseases of the Skin, Chapter 8)

When a nonsuppurative paronychia is present, moniliasis caused by *Candida albicans* is to be suspected, especially in fruit pickers and handlers, dishwashers, housewives, dentists and others whose nails are wet during prolonged periods.

Because of the close resemblance of onychomycosis to psoriasis, the diagnosis always depends on microscopic and cultural identification of the fungi. Positive cultures are obtained from 1 of every 5 who have the disease.

Trauma. Schwartz, Tulipan and Peck have considered in detail the effects of trauma to the nails Hemorrhage beneath the nail plate (subungual hematoma) may be caused by a bruise, and the nail may subsequently be loosened and fall away. Deep splinters may cause longitudinal white streaks, a form of leukonychia. Spoon-shaped nails (without regrowth) may form; or in elderly patients such a nail may

skin over the pad of the finger sends off fibrous bands or fibrils which are attached to the parts beneath. An infection of the skin can pass through it and involve the fatty tissue beneath. The pus is often unable to break through the skin. Since the fibrous bands prevent swelling, it burrows and involves the periosteum and thence to the region of the joint, where it may enter the sheath. Once the pus is within the tendon sheath it extends as far as the sheath goes

In pursuit of his labors, man is exposed to various hazards that deform his body and cripple his hands The changes which affect the hand under the influence of mechanical, chemical, thermal, electric and atmospheric stimuli are numerous. These changes may be characteristic of certain trades, so that they may be regarded as trade stigmas For instance, hands which are in constant contact with water may be affected by an alteration of the skin, characterized by softening, chapping and often ulceration, with veritable destruction of the parts.

The trade stigmas of the hands have been classified by various outlines. Oppenheim, long ago, enumerated these stigmas as stains or coloring A more recent classification has been enumerated by Schwartz, Tulipan and Peck as: stratifications, excoriations, telangiectases, nail changes, pigmentation, callosities, bursae, cicatrices and tattooing

The nails frequently exhibit trade stigmas. The right thumbnail in women who remove the indigo fruit from its shell is long In watchmakers and clockmakers this nail is short The nails of laundresses and lens grinders are short and cracked

The hands become covered with particles of the material used at the place of work. Thus deposits of coal dust forming indelible blue-black scars enable one to recognize the coal miner who, when working, soils every scratch with coal dust. Similar deposits in the skin are found among metal workers, millers, and stonemasons

Superficial wounds, excoriations and rhagades are to be found among seamstresses, dressmakers, cobblers and glassworkers. The hands of glassblowers commonly exhibit wheals, flat plaques, rhagades and warts. (For further discussion of trade stigmas and mutilating affections of the hands, see Chapter 24)

Ankylosis of the Hand. The finger and wrist flexors are stronger than the extensors. The adductors of the thumb are stronger than the abductors. The wrist or fingers stiffen in a flexed position, or the thumb in an adduction deformity when prevented from use

Prolonged immobilization is probably the most frequent cause of stiffness in the hand, because of the necessity of continuous splinting in injuries of the arm or the hand In nerve injuries, in loss of substance, and in suppurations such as palmar abscess, the usefulness of the hand is sometimes totally lost Without the use of the hand grasp, all the wide excursions of the elbow and shoulder are useless Impediment in the shoulder or the elbow also limits use of the hand.

A *snapping finger* is produced by some obstruction to the action of the long dorsiflexor tendons under the ligament across the joint If painful or disabling, determination of the nature of the obstruction is made.

Ankylosis or Loss of the Thumb. Without use of the thumb the hand is left with only parallel digits, and the palm is the only opposing force in the act of gripping.

The fingers bear the evidence of the influence of the cerebral cortex on the acquisition of willed movements. They possess the tactile senses so necessary for the most technical accomplishments of the hand or the coarser squeezing duties which require strength and action. Without the fingers or thumb the hand becomes useless. Without individual action the finer functions of the fingers are lost. Therefore the interruption of perfection in one digit disturbs the synchronization and proficiency of the entire hand.

Nutritional Deficiency. Egg-shell nail is commonly seen in avitaminosis A Koilonychia (spoon nails) may be present in association with dysphagia, glossitis and [illegible] ise. Beau's [illegible] malnutri-

Changes in Dermatoses. LICHEN PILARIS SEU SPINULOSUS In lichen pilaris (keratosis pilaris) atypical nail changes may occur.

KERATOSIS FOLLICULARIS (DARIER'S DISEASE). The nails may become friable and split, and onychauxis, onychogryposis, paronychia and longitudinal ridges may develop

EXFOLIATIVE DERMATITIS Onychomadesis is of frequent occurrence in exfoliative dermatitis, as in drug sensitivity However, regrowth often takes place.

ALOPECIA AREATA In alopecia areata interruption of nail growth producing Beau's lines, thinning, and increased friability may be present. Regrowth almost invariably occurs.

ECZEMA. Nail changes in eczema are highly varied, ranging from minor disturbances of growth and distortion of structure to almost complete erosion and onychomadesis. Suppurative paronychia is frequently associated with eczema.

Nail changes occasionally occur in psoriasis.

Tumors Involving the Nails. Nails can be deformed in varying degrees by verruca, clavus, and exostoses of the phalanges A chondroma in the terminal phalanx causes deformation of the nail A glomus tumor may arise immediately beneath the nail bed, on which it may encroach, to become visible as a bluish discoloration under the nail plate A glomus tumor is exquisitely painful A simple angioma may be observable as a red discoloration in the nail bed or about the nail Occasionally, a melanoma originates from the matrix or nail fold. A fibroma may be observed beneath the nail bed or about the nail

DISEASES AFFECTING THE ARM AND HAND AS A WHOLE

Arachnodactyly. The individual afflicted with arachnodactyly according to Parker and Hare is tall, with excessively long arms and legs, long, thin, spider-like hands, meager subcutaneous fat, under-developed, atonic musculature and often ectopia lentis The emaciation accentuates the bony landmarks, and these in turn serve to emphasize the disproportionate length of the extremities as compared to the trunk The delicately elongated, spider-like fingers give this syndrome its name. The feet and toes are likewise long and slender Deformities of the joints are common Pes planus, contractures, hammer toes, webbing and sometimes abnormally mobile patellas occur The frequently associated scoliosis, kyphosis, winged scapula and deformities of the sternum are considered to be the result of the laxity of the ligaments and atonic musculature. The skull of the arachnodactylic patient tends to be dolichocephalic with prominent supra-orbital ridges, frontal bossing, a pointed chin and either a prominent or a broad, somewhat flattened nose The face is usually drawn, wrinkled and old looking, often with a melancholy expression. The ears are frequently enlarged Approximately 50 per cent of the patients have a partial dislocation of the lens, usually upward Congenital heart anomalies frequently accompany the disease and consist mainly of a patent foramen ovale and other interauricular septal defects In the infant or rapidly growing child this syndrome may resemble rickets The abnormally long and slender extremities, the absence of flared epiphyses, normal blood calcium and phosphorus, and perhaps obscure anomalies in the parents, should lead one to suspect arachnodactyly The symptoms of weakness, fatigue, moderate dyspnea on exertion, malnutrition and a coarse systolic murmur in early childhood may focus attention on the cardiovascular system to the exclusion of what appear to be lesser anomalies. This syndrome is not considered to be of endocrine origin

Venous Obstruction in Upper Extremity. An arm of an otherwise healthy person may become diffusely swollen and discolored. It has been suggested that

become wrinkled, and hyperkeratosis of the periungual tissues may form and malignant degeneration with the formation of epithelioma may ensue

Chemical Agents There are a number of chemical agents, among which are included soap, nail polish, polish remover, nail polish undercoats, dyes and industrial chemicals, which injure the nails Pigmentation or discoloration of the nail may be produced by contact with *topical medicaments* such as gentian violet, mercurochrome, silver nitrate, chrysarobin, silver-containing compounds, arsenic, tobacco, and many chemicals used in industry However, in industry the offending substances are known and the hands are usually protected

Soaps, nail polish bases (undercoat), fabric fibers (wool, silk) and chemicals cause allergic lesions after repeated contact The lesions vary from leukonychia and minor ridging to marked destruction of the nail plate and inflammation of periungual and subungual tissues Often these lesions resemble those of mycotic infections and psoriasis

Nail discoloration and dystrophy may be due to nail polish and nail polish bases or undercoats Sulzberger and others have observed the clinical features associated with allergic eczematous reactions of the nail bed due to synthetic resin-rubber undercoats and they have enumerated the following features: (1) a discoloration, diffuse or punctate, of the distal portion of the nail which ranges from yellow through blue to black; (2) separation of the distal portion of the nail from its bed (onycholysis); (3) subungual hyperkeratosis, (4) erythema, edema and scaling of the fingertips under the free edge of the nail, and subjective symptoms in the areas, may occur if the nail which has an undercoat is subjected to repeated trauma

Nail discolorations occur as the result of injury to the tips of the fingers. The nails become separated from their beds—a condition known as onycholysis. Nails may become discolored and may separate if repeatedly subjected to external heat A splinter of wood, glass or metal often tears the nail away from its bed and causes discoloration and perhaps separation

Trauma and Physical Agents. Workers who use power-driven drills or hammers are subject to development of hyperkeratoses beneath the nails Gardeners, laborers, textile workers, and those who handle wool often suffer from nail infections following trauma (Schwartz, Tulipan and Peck have considered in detail diseases of the nails in industry)

[illegible] the first observable [illegible]e [illegible]h

as those of phosphorus and iodine

Enumeration of the early disturbances of nail growth caused by irradiation according to Schwartz are (1) thinning, softening and increased friability of the nail, (2) longitudinal splitting, (3) discoloration and (4) varying degrees of atrophy. As time passes after irradiation, transverse ridging (Beau's lines) and loss of the nail occur.

Vascular Disease. In both vasospastic and obliterative vascular disease the nails undergo specific changes indicative of the lack of adequate circulation.

In vasospastic conditions, according to Allen, a pterygium develops (1) the nail fold becomes thinner and the cuticle widens; (2) the normally distinct boundary between nail fold and cuticle, as well as that between cuticle and nail plate, is lost.

Pterygium is a common condition of the last two toe nails of apparently normal individuals It is also common, however, in Raynaud's disease and scleroderma. [illegible] the nail plate The [illegible], thick, rough, dark [illegible]al nerve lesions, as [illegible]

limb against resistance. The muscle bellies can be felt and sometimes seen (Fig. 6-56B).* (Superior gluteal nerve supply, L_4, L_5, S_1.)

The Hip Joint and Monarticular Disorders. The hip joint is a ball and socket joint. The functions of the hip are mobility and support. For the necessary support and limitation of extent of movements of the hip, there are strong bandlike ligaments uniting

Fig. 6-54 Adductor muscles of leg Lying on back with leg extended and abducted, patient attempts to adduct the leg against resistance The muscles can be seen and felt Nerve supply L_2, L_3, L_4 (obturator nerve)

the bones. In the upright position the center of the weight of the body falls in front of the axis of rotation of the hip joint When a person falls it is usually forward. Falls in any other direction are indicative of complete loss of balance

The head of the femur is 2 inches (about 5 cm) in diameter and spherical in shape. The acetabulum is deep The joint is airtight, and the femur is held in place by suction and ligaments

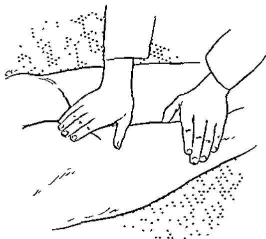

Fig 6-55 Gluteus maximus muscle Lying with face downward, abdomen and leg flat on firm surface, patient attempts against resistance to lift knee upward. The muscle can be seen and felt Nerve supply L_4, L_5, S_1, S_2 (inferior gluteal nerve)

The great pressure to which the articulating surfaces of the hip joint are subjected requires special lubrication of these surfaces, and this is supposed to be furnished by the ligamentum teres and haversian glands

Congenital Malformations of the Hip. In the anamnesis a history of limping or of waddling from earliest childhood can be obtained.

DISLOCATIONS. Congenital luxations, or dislocations, of the hip are most frequently posterior in position and are characterized by excessive mobility of the thigh. The manifestations of this deformity are no eversion, no flexion on lying down, and usually a high grade of lumbar lordosis on standing The acetabulum may be shallow. The head of the femur is deformed, and it occasionally is superior, but

* Acknowledgment is made to the Controller of Her Britannic Majesty's Stationery Office for permission to make line drawings of photographs of muscles in action in War Memorandum No 7, reprinted 1945

Sartorius. The patient lies on the back with the hip laterally rotated and tries to flex the knee against resistance. The muscle belly can be felt and sometimes seen (Fig 6-52). (Femoral nerve supply, L_2, L_3.)

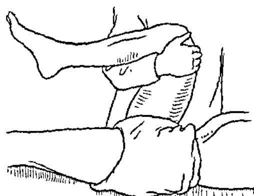

Fig 6-51 Iliopsoas muscle. Lying on back with the knee flexed, while the leg is supported at less than a right angle between the thigh and trunk Patient attempts to flex the hip against resistance Nerve supply L_1, L_2, L_3 (femoral nerve)

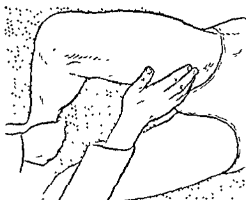

Fig 6-52 Sartorius muscle Lying on back with leg to be tested laterally rotated at the hip patient attempts to flex the knee against resistance Nerve supply L_2, L_3 (femoral nerve)

Quadriceps Femoris The patient tries to extend the knee against resistance The muscle bellies can be felt and often seen (Fig 6-53) (Femoral nerve supply, L_2, L_3, L_4.)

Adductors The patient lies on the back with the knee extended and tries to adduct the leg against resistance The muscle bellies can be felt (Fig 6-54). (Obturator nerve supply, L_2, L_3, L_4)

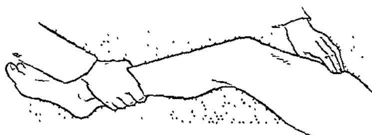

Fig 6-53 Quadriceps femoris muscle Lying on back with knee flexed, patient attempts to extend the knee against resistance The muscle can be seen and felt Nerve supply L_2, L_3, L_4 (femoral nerve).

Gluteus Maximus. In the prone position the patient tries against resistance to lift the knee. The muscle belly can be felt and often seen (Fig. 6-55) (Inferior gluteal nerve supply, L_4, L_5, S_1 and S_2)

Gluteus Medius and Minimus and Tensor Fasciae Latae (Rotation). To test internal rotation at the hip joint, the patient is in the prone position with the knee flexed to a right angle, and tries to carry the foot laterally against resistance. The muscle bellies can be felt and sometimes seen (Fig 6-56A). (Superior gluteal nerve supply, L_4, L_5, S_1.)

Gluteus Medius and Minimus and Tensor Fasciae Latae (Abduction). To test abduction, the patient lies on the back with the leg extended and tries to abduct the

Coxa vara is to be distinguished from (1) congenital dislocation of the hip, (2) beginning coxitis and (3) the effects of trauma.

Infections of the Hip Joint. Hip disease, coxitis or coxalgia in its early stage is characterized by pain, limitation of motion and limping The pain may be limited to the hip itself or referred. The hip is supplied by branches of the anterior crural, sciatic and obturator nerves, and since these also supply the region of the knee, disease of the hip often causes pain to be referred to the region around the knee joint.

In an early stage the limitation of motion is due to muscular contraction The limb is held in a position of flexion, abduction and slight external rotation. In mild cases the limitation is present as a reduction only in the normal extent of movements The abnormal changes are recognized by inspection, measurements, and comparison with the opposite healthy limb.

On inspection from behind, the gluteal fold is small over the affected side and the buttock is flattened The flattening of the buttock is caused by the flexion of the hip. An inequality in the lower limbs, whether due to shortening or to malposition, such as flexion, will be visible at once by an inequality of the gluteal folds, one being higher than the other. Flexion deformity is recognized, when the patient is standing, by the bending at the hip joint and by the lordosis or hollowing of the back. In flexion deformity of the hip, when recognized, the degree can be measured while the patient is in the recumbent position by the difference in the length of the legs.

The patient being flat on the back, the pelvis is made level by seeing that a line joining the two anterior iliac spines is at right angles to the median line. If abduction is present, the limb points away from the median line It cannot be brought straight down parallel with the sound leg without tilting the pelvis If measured from the umbilicus to the internal malleolus, the affected leg measures more than the sound one. This is called apparent lengthening. If when both limbs are placed in the same degree of abduction and are measured from the anterior iliac spine to the internal malleolus they measure the same, there is no real shortening.

In advanced disease, adduction is commoner than abduction. Adduction produces an apparent shortening, as shown by measurement from the umbilicus to the internal malleolus; if the sound limb is placed in the same degree of adduction as the infected one, the distances from the anterior iliac spines will show no actual shortening unless there is a loss of bone or displacement at the hip joint The pelvis, instead of being tilted down on the diseased side, is tilted up Flexion is usually more marked and the foot is usually inverted instead of everted.

In the diagnosis of the acute inflammations of the hip and its neighborhood, it is necessary to distinguish acute inflammations of the hip joint itself from osteomyelitis of the shaft of the femur. In the latter, cautious passive movement of the hip is possible and there is local tenderness below the trochanter. Also to be distinguished are iliac abscess, femoral or inguinal lymphadenitis and acute phlebitis of the femoral vein

If acute arthritis is present, it may be due to acute rheumatic fever, to other kinds of infectious arthritis, to syphilitic arthritis or to very acute tuberculous coxitis

CHRONIC COXITIS Of the chronic infections of the hip joint in childhood, by far the most important is tuberculous coxitis, the common hip-joint disease of childhood In adults nontuberculous arthritis is commoner including avascular necrosis

In *tuberculous coxitis* the child begins to show a painful limp, the gluteal fold disappears, and the muscles of the thigh begin to atrophy. Sometimes the child complains of pain in the knee rather than in the hip, but examination of the knee joint does not reveal anything abnormal there. On examination of the child lying on its

usually posterior, to the acetabulum. It can be moved backward and forward on the pelvis. The neck of the femur is twisted on its shaft.

There is shortening of the leg on the affected side when measurement is made from the anterior superior iliac spine The anterior iliotrochanteric angle is diminished or lost The tip of the trochanter lies abnormally high, above the Roser-Nélaton line. By palpation it can be recognized that the head is not in its normal position beneath the femoral artery. The superior border of the trochanter is on a level with the anterior superior iliac spine. Roentgenologic examination is necessary to ascertain accurately the position of the head and whether or not the bones possess their normal shape

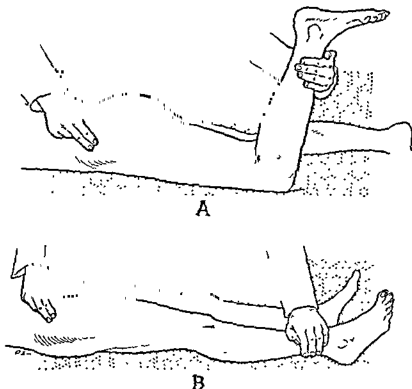

Fig. 6-56 A, gluteus medius and minimus and tensor fasciae latae muscles as internal rotators Lying with face downward, belly flat, leg flexed at knee, patient attempts to carry the foot laterally against resistance The muscle can be felt Nerve supply L_4, L_5, S_1 (superior gluteal nerve).

B, gluteus medius and minimus and tensor fasciae latae muscles as abductors Lying flat on back on firm surface, legs extended, patient attempts against resistance to abduct the leg The muscle can be felt Nerve supply L_4, L_5, S_1 (superior gluteal nerve)

The abnormal mobility distinguishes congenital dislocation of the hips from bilateral coxa vara due to rickety curvature of the femur Poliomyelitis may cause a paralytic limp resembling congenital dislocation but the roentgenologic examination reveals the head of the femur in the acetabulum

Coxa Vara. Coxa vara is a curvature of the neck of the femur, causing adduction of the thigh and apparent shortening of the leg The changes in the position of the neck of the femur in coxa vara may be due in childhood to rickets, in later life to the carrying of heavy burdens or, more rarely, to osteomalacia. The coxa vara of childhood is usually bilateral; that of adults may be either unilateral or bilateral The signs of coxa vara are (1) anterior position and abnormally high position of the trochanter, (2) lateral rotation and limitation of abduction of the thigh, (3) medial rotation and flexion, and (4) when unilateral, shortening and limping

Roentgenograms are diagnostic and should be made unless it is unwise to move an aged, infirm patient

Ankylosis of the Hip Joint. Complete ankylosis of the hip joint is somewhat compensated by a flexible lumbar portion of the spinal column The unfavorable positions of ankylosis of the hip joint are considered to be severe flexion with adduction and internal rotation, since these positions interfere with standing or walking because of the shortening that they produce, which affects lateral equilibrium.

A favorable position of ankylosis is that approaching extension in the long axis of the body. In this position standing and walking are possible but sitting is hampered. Ankylosis in flexion, however, is favorable to the sitting position

Varying degrees of ankylosis of the hip are caused by (1) Contusions or sprains which may result from a severe blow or fall with the impact over the trochanter or imparted through the shaft A single dislocation does not induce more than temporary ankylosis Repeated dislocations may cause stiffening. (2) Fracture of the acetabulum, or of the head or the neck of the femur, may cause stiffness (3) Continuous immobilization over a long period of time may permit of atrophy, adhesions and stiffness. (4) Suppuration in the hip joint usually results in complete ankylosis or a disability just as bad, resulting from joint pain on movement. (5) Rheumatic arthritis in its many forms frequently affects the hip joint

Adduction in a leg that is fully extended at the hip produces disability of standing, balancing, walking, jumping and running The disability in all these activities is increased by the shortening effect, which increases as the adduction deformity increases.

In flexion deformity, abduction is an advantage because it decreases the lengthening effect unless there is external rotation

Internal rotation increases the disability in the performance of all the duties of the leg Outward rotation produces no disability so long as the toes can reach the normal vertical weight-bearing line. When the toes cannot reach the midline, disability becomes more severe, and especially when there is flexion deformity, outward rotation adds to the disability Internal rotation with flexion brings the toes into a more convenient position for weight bearing (McBride)

Tumors of the Hip and Thigh. Of the neoplasms of the hip and thigh those involving the muscle include angioma, fibroma and sarcoma, all of which must be differentiated from tuberculous myositis, gummatous myositis and muscle hernias. Those originating in the bone include cartilaginous exostoses, enchondromas, osteomas and myeloid sarcomas. Such tumors of the bone must be distinguished from osteomyelitis and fractures A spontaneous pathologic fracture of the bone may occur in sarcoma

A positive diagnosis as to the nature of a tumor is established by biopsy

Diagnosis of Hip-Joint Disease. In hip-joint disease there may be no symptoms referable to the hip The pain may be referred to the knee As the disease advances there develops a limp as the result of a shortening of the leg on the affected side. As the leg shortens the pelvis tilts and a scoliosis develops

In a limp from a congenital dislocation of the hip the patient steps forcibly forward on the affected side In these limps the patient obviously is not afraid of producing pain in the leg or foot, but limps in order to place himself more firmly on the affected leg If the dislocation is bilateral, a waddling gait develops A limp may result from painless rigidity of one hip joint, as from a healed coxitis, injury or rickets, the whole extremity, including one half of the pelvis, being moved forward as a unit Bilateral stiffness of the whole lower extremity occurs in extreme bilateral coxa vara, rheumatoid arthritis and from the prolonged use of casts. A limp results when there is pain in some one of the joints on the affected side on movement, as a result all the joints of that side may undergo muscular fixation. The patient avoids

back with the legs straight out, there is obvious lordosis of the lumbar region of the spinal column. If this lordosis is overcome by strong flexion of the thigh of the healthy side, there will be involuntary flexion of the thigh of the affected side when tuberculous coxitis exists (Thomas' test). There is fixation of the affected extremity and the pelvis, these parts moving as a whole

During the progress of the disease a cold abscess may form, pointing in the following order of frequency: (1) in front, below the anterior superior iliac spine, (2) lateralward and (3) backward. Tenderness on pressure can be elicited at the front of the joint below the middle of Poupart's ligament, and compression from the trochanter is painful

Roentgenologic examination in the earliest stages of tuberculous coxitis may not reveal definitely positive findings except for an osteoporosis due to disuse After the disease has advanced and has involved the cartilage and bone, the roentgenologic findings are characteristic and diagnostic

Tuberculous coxitis is distinguished from (1) subacute forms of simple infectious coxitis, (2) chronic infectious arthritis, (3) congenital dislocation of the hip, (4) the different forms of coxa vara, (5) caries of the spinal column and of the pelvis, with cold abscess formation, (6) periappendicular abscess and perinephric abscess, (7) hydrops of the bursa iliaca, (8) sciatica and other neuralgias and (9) hysteria (Brodie's joint).

Nontuberculous chronic coxitis may be either rheumatoid arthritis or osteoarthritis Occasionally the hip is involved in a neuropathic arthropathy such as tabes dorsalis or syringomyelia.

Avascular degeneration of the head of the femur may occur from unknown causes The course is a chronic one characterized by pain which is often referred to the knee. The roentgenologist can usually suggest the correct diagnosis

Injuries of the Hip Joint. If, after an injury to an aged person in the home, roentgenologic examination is not readily available, the following procedures may be helpful diagnostically The position and attitude of the injured extremity should be inspected, for this inspection alone will often give a clue to the nature of the injury. Inspection is followed by measurements, to ascertain whether or not there is shortening, and if so, whether it is supratrochanteric or infratrochanteric

The position of the trochanter is determined by means of the Roser-Nélaton line or by outlining Bryant's triangle The Roser-Nélaton line joins the anterior superior spine of the ilium to the tuberosity of the ischium, normally the greater trochanter of the femur lies in this line. Bryant's triangle is constructed while the patient is lying on the back Let fall a perpendicular line from the anterior superior spine to the table The other side of the triangle is a line joining the anterior superior spine and the tip of the greater trochanter The base of the triangle is a line running horizontally from the tip of the trochanter to the perpendicular line In fracture of the femur the trochanter is elevated, when the neck of the femur is fractured, the base of the triangle is shortened

If it is determined that there is shortening of 1 inch (about 2 5 cm) and there is good reason to believe it was not present before the injury, a dislocation or a fracture has occurred If the shortening is supratrochanteric, there has been a dislocation or a fracture of the neck of the femur, if it is infratrochanteric, there has been a fracture below the tip of the trochanter If the trochanter is abnormally high, it indicates a dislocation or a fracture of the neck If the trochanter occupies its normal position, usually there is no dislocation or, if there is one, it must be situated below the trochanter.

The active movements of the leg are examined by desiring the patient to lie flat on the back and lift the injured leg. If the injured leg can be lifted, there is no dislocation or fracture. If the thigh can be flexed with difficulty, without raising the heel from the bed, an impacted fracture may have occurred, in which event there will be limitation of active medial rotation

thus moved and if such an attempt is made, a sharp pain ensues. A cirsoid femoral vein is soft and yields to pressure and will collapse when the leg is elevated.

THE KNEE JOINT

The knee joint is primarily a hinge joint and is firmly and strongly braced by ligaments. Its movements are extension and flexion. It can be extended to a straight line and flexed until the thigh and the upper portion of the leg come in contact. Any detectable rotary movements of the knee when fully extended are associated with injuries

The bony landmarks of the knee are the patella, the two epicondyles of the femur, the tibia and the fibula.

The patella is pointed distally where the tendo patellae is attached, and is slightly convex on its proximal border. Its lateral edges are prominent, owing to the lack of tissue over this bone With the limb extended and quadriceps muscle relaxed, the patella can be moved in all directions except distally There is a depression above the patella When the muscle contracts, this depression is filled by the rectus, and the muscular swells on each side produced by the vastus internus and externus are visible. When the quadriceps muscle is contracted, the tense tendo patellae becomes evident, when the muscle is relaxed, the soft fatty pad beneath the tendon can be felt.

About halfway between the patella and the tubercle of the tibia can be felt a groove, the line of the joint and the location of the semilunar cartilages. On the lateral side posteriorly, opposite the level of the tibial tubercle, can be felt the head of the fibula Running proximally from the fibula is the tendon of the biceps. In front of the biceps can be seen and felt the iliotibial band of the fascia lata. It is difficult to distinguish the joint line of the knee by palpation.

Posteriorly, with the leg extended, the condyles of the femur can be outlined and recognized The medial is the more prominent The tubercle of the tibia, situated at the insertion of the patellar ligament, can best be seen and felt when the tendo patellae is relaxed. The tubercle of the tibia is not to be confused with the external tuberosity of the tibia, which is proximal and lateral to the tubercle, laterally from the external tuberosity and somewhat distally can be seen and felt the head of the fibula Posteriorly when the knee is extended is seen the fullness of the popliteal space

Extending about 2 inches (about 5 cm) above the patella is the subfemoral or suprapatellar bursa

The capsular structures of the knee in their lower ends are attached to the tibial tubercle, but above, their attachments are far removed from the joint. These structures are so strong and thick that pus from within does not come through but goes around them In maximal extension the bulk of the patella rises above the articular surface, and connecting its upper edge with the anterior surface of the femur is only the thin capsular ligament, hence effusions into the joint bulge upward at this point

Functional Testing of the Muscles About the Knee Joint. *Hamstring Muscles.* The patient in the prone position tries to flex the knee against resistance The tendons of the biceps (laterally) (Fig 6-57A) and semitendinosus (medially) (Fig 6-57B) * can be felt and usually seen (Nerve supply, L_4, L_5, S_1, S_2 Sciatic nerve)

The Knee and Monarticular Disorders. *Infections of the Knee Joint.* The knee joint is affected by both acute and chronic inflammations

In the *acute inflammations* of the knee joint the etiology may be that met with in acute arthritis of any of the joints An acute gonitis is nearly always of infectious nature Gonococcal gonitis is rare, it may localize in one knee joint, and sometimes

* Acknowledgment is made to the Controller of Her Britannic Majesty's Stationery Office for permission to make line drawings of photographs of muscles in action in War Memorandum No. 7, reprinted 1945.

using the affected extremity as a support. The body becomes inclined toward the healthy side.

The diagnosis of disease of the hip joint is made from the history, and the physical and roentgenologic examinations. However, in some instances the exact diagnosis awaits bacteriologic and histologic studies.

THE THIGH

The thigh is composed of the femur and three main sets of muscles, and is supplied and traversed by the femoral vessels and sciatic and anterior crural nerves The femur serves as a support The muscles move the thigh on the trunk, and the leg on the thigh. The thigh muscles are extensors, flexors and adductors

The deep fascia (fascia lata) of the thigh is a strong layer which completely invests the muscles of the thigh and covers the gluteal region Over the saphenous opening the fascial layer is thin and is known as the fascia cribrosa

The *femoral (Scarpa's) triangle* occupies approximately the proximal third of the thigh Its base proximally is formed by Poupart's ligament, its lateral side by the sartorius muscle, and its medial side by the adductor longus Its floor is formed by the iliacus, psoas, pectineus, sometimes a portion of the adductor brevis, and the adductor longus muscles In the depths of this triangle course the femoral artery and vein, the anterior crural nerve, the long saphenous vein and numerous lymphatic vessels. At its proximal and medial part is the saphenous opening, at which femoral hernias make their appearance Psoas abscesses follow the tendon of the psoas muscle down and make their appearance in Scarpa's triangle Also pus from hip-joint disease comes to the surface at the upper part of the triangle on one side or the other of the femoral artery The apex of Scarpa's triangle is a favorite site for ligation of the femoral artery

The lymph nodes of the groin are separated into the superficial and the deep sets The nodes of the superficial set are along Poupart's ligament and along the blood vessels The nodes of the groins drain the lower anterior half of the abdomen, the genitalia, the lower limbs, and the anal, gluteal and lumbar regions

The deep lymph nodes are not constant, and rarely become the seat of infection; but when chronically inflamed, such a node may be mistaken for a femoral hernia. The nodes of the groin communicate with the external and common iliac nodes

Femoral Hernia. Femoral hernia, although often considered to be acquired, is probably the result of a congenital defect The hernia descends through the femoral canal beneath Poupart's ligament to make its appearance at the saphenous opening on the thigh. The saphenous opening has its center 1½ inches (about 4 cm) below and to the outer side of the spine of the pubis The femoral canal represents the narrow space between the femoral vein and the inner wall of the femoral sheath Weakness of the ligamentum lacunare (Gimbernat's ligament), which forms the medial boundary of the femoral ring, is an important factor in the development of a femoral hernia.

Femoral hernia occurs less frequently than inguinal hernia, and more often in women than in men.

The hernia appears in the soft tissues in the femoral region. Such a hernia is smaller than an inguinal hernia and may be present without a mass or other external manifestation or even without the patient being aware of it When strangulation is present, and it occurs often, outward manifestations may be minimal unless the palpating finger presses on the hernia, which is often buried in femoral fat If a loop of bowel is strangulated, however, the manifestations of intestinal obstruction are obvious.

A femoral hernia large enough to contain intestine is obvious. Femoral hernias of this size are not common In an obese patient a strangulation of a small femoral hernia may not be diagnosed until operation for intestinal obstruction is performed.

A small hard femoral hernia has to be differentiated from an *enlarged lymph node, a small lipoma* and *a cirsoid femoral vein* Usually when lymph nodes are enlarged, several nodes are affected. A small lipoma usually can be grasped in the hand and separated from the deep-lying tissue, whereas a femoral hernia cannot be

Stiffness of the knee may be extremely persistent following immobilization of fractures of the leg or thigh Permanent stiffening may occur as a result of atrophy of cartilage, synovial shrinkage and muscular contraction.

Trauma to the knee joint may be followed by loosening of a cartilage from one of the condyles of the femur (roentgenologic examination, palpation); or if there has been a twist of the joint, especially when the thigh has been rotated outward when the leg is fixed, there may be a loosening and displacement of one meniscus, usually the medial meniscus. This causes a disturbance of function of the joint described as internal derangement

Internal Derangements of the Knee. The evidence for internal derangements of the knee is established by the following measures. (1) Eliciting the history ascertains the mechanics by which the lesion was made and the amount and type of pain, swelling, locking or catching, instability, weakness, and limitation of joint motion. Many derangements of the knee which seem of little consequence become disabling owing to the rapid atrophy of the quadriceps muscle, as a result of injuries of the knee. (2) By inspection the degree of atrophy of the quadriceps muscle is seen as well as the range of active and passive motion of the joint, the presence or absence of swelling and fluid, and the location of tenderness if observed Then tests are made for lateral and anteroposterior instability. (3) The roentgenologic examination is usually of value only in a negative way, since the majority of internal derangements affect only the soft tissues, however, it is important in establishing the presence of loose bodies, fractures and calcified meniscuses

Internal derangements of the knee may result from (1) injuries of semilunar cartilages, such as tears, dislocations, cysts, discoid cartilage and calcified meniscuses, (2) loose bodies in the joint such as detached osteophytes, synovial osteochondromatosis, osteochondritis dissecans and osteochondral fractures; (3) injuries of the ligaments; (4) affections of the soft tissues such as cysts and adventitious bursae, hypertrophic infrapatellar fat pads and intra-articular adhesions; (5) fractures of the tibial spine and (6) recurrent dislocations of the patella.

SEMILUNAR CARTILAGES *Tears of the Semilunar Cartilages* These are usually found in young men The history consists of the triad of pain in the knee, swelling of the knee and locking or catching of the knee The triad begins after a twisting injury with the tibia abducted on the femur in case of tears of the medial semilunar cartilage and adducted on the femur in case of tears of the lateral cartilage. The medial semilunar cartilage is injured 10 times more frequently than the lateral semilunar cartilage.

Hypermobile or Dislocating Semilunar Cartilages These probably constitute a definite entity and on occasion can cause locking, but they are rare. Hypermobility may be demonstrated by grasping the anterior end of the cartilage and displacing this toward the midline.

Cysts of the Semilunar Cartilages These are extremely rare, and when present, almost invariably involve the lateral semilunar cartilage. They can often be palpated on the lateral side of the knee.

A Discoid Semilunar Cartilage This represents a congenital defect which usually affects the external semilunar cartilage and is rare. This condition is usually manifest clinically early in life, and the child complains of a snapping sensation in the knee when walking

Calcified Meniscuses These are sometimes seen in older persons and occasionally cause a popping or snapping sensation This condition can usually be demonstrated roentgenologically

LOOSE BODIES. These are the second commonest cause of internal derangement of the knee. The common symptom is locking or catching. In the majority of cases loose bodies can be demonstrated by anteroposterior, lateral or intercondylar notch roentgenograms The bodies may be palpated in the suprapatellar pouch or about the articular surface of the joint. Loose bodies may be the result of:

it causes suppuration there. In polyarthritis due to rheumatic fever the knees are frequently involved

In all acute infections there is evidence of effusion into the knee joint with floating patella, usually there is also some thickening of the capsule, which can be felt in thin persons at its fold of reflection when the affected knee is compared with the healthy knee *Sometimes the cartilages and bones are involved,* as revealed by roentgenograms

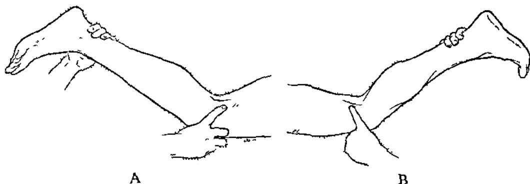

Fig 6-57 Hamstring muscles (semitendinosus and biceps femoris muscles) A, laterally, biceps muscle B, medially, semitendinosus muscle Lying on smooth, firm surface with face downward, patient attempts to flex the knee against resistance The tendon can be felt and seen Nerve supply L_4, L_5, S_1, S_2 (sciatic nerve)

Such acute gonitis must be differentiated from (1) acute prepatellar bursitis, (2) hydrops intermittens of the knee and (3) acute osteomyelitis of the lower end of the femur or of the upper end of the tibia.

Many different forms of chronic inflammation of the knee joint are met with clinically Common causes of chronic effusion into the knee joint are (1) chronic rheumatoid arthritis and (2) tuberculosis.

Effects of Trauma. In falling, the knee often strikes first, and there may be an injury to the bursa prepatellaris, to the patella, or to the knee joint itself

An effusion into the bursa is recognizable from its location and limitations away from the joint When there is an effusion into the knee joint itself, the knee cannot be fully flexed, and there is swelling around the patella, the grooves on both sides of this bone being filled out There may be a transverse swelling above the patella where the joint cavity extends up beneath the tendon of the quadriceps muscle. Effusion into the joint lifts the patella from the condyles of the femur If pressed with the finger down upon the bone, the firm substratum can be felt when it is reached; if the pressure is taken off again, the patella will once more float

In a sprain some of the ligamentous or cartilaginous structures may become permanently damaged The lateral ligaments are the more commonly injured The internal lateral ligament is more commonly injured than the external, and the manifestations may resemble that of injury to the semilunar cartilage The sprain may be severe enough to produce a tear into the bony tissue and in such instances longer and more thorough immobilization will have to be instituted, and thus stiffness of the joint is more likely to occur

Other results *of injury to the knee are those of rupture of the crucial* ligaments, or tearing of the synovial membrane so as to leave a fringe that may be caught in joint action and create chronic synovitis.

True dislocation of the knee *joint is rare and is produced* by extreme violence It is common, however, for the patient to believe that the knee has been dislocated [illegible] or a sprain. True dis- [illegible] *ssociated* with fracture.

tendon Behind the knee joint, in the popliteal space or poples, swelling due to aneurysm is not uncommon; its pulsation quickly differentiates it from (1) distended bursa here, (2) lipoma and (3) cold abscess.

Of the tumors below the knee, sarcoma of the upper end of the tibia or of the fibula is not uncommon. The roentgenogram in such cases is characteristic. Cartilaginous exostoses may also occur near the extremities of both the tibia and the fibula.

THE LEG

The two tuberosities of the tibia, the tibial tubercle and the head of the fibula, can be seen or palpated

The tibia is triangular in shape, with a sharp edge—the crest or shin—forward and a flat surface medially. Thus it participates in the formation of two surfaces, the medial and the anterior, of the leg The medial surface is subcutaneous and extends almost the full length of the leg to the internal malleolus. The lateral surface has the extensor muscles between it and the fibula The fibula, a short distance below its head, becomes covered by the peronei muscles and becomes subcutaneous only in its lower anterior fourth The proximal portion of the leg is largely muscular, but at its distal portion it is mainly tendinous

The muscles of the leg can hardly be considered separately from those of the foot. The long muscles support the arch of the foot, flex, extend, abduct and adduct the foot. Adduction of the foot is associated with a limited amount of rotation.

The individual muscles perform compound action, not a simple one. They act on two joints, the ankle and subastragaloid If the ankle joint is stationary, they abduct and adduct the foot If the subastragaloid joint is stationary, they flex and extend the foot, but if both joints move, as is usually the case, combined action of the muscles accomplishes this feat

The Action of the Muscles as Flexors and Extensors. The movements of the foot when strength is not required are performed by the flexor and extensor groups of muscles. The powerful calf muscles aid especially in lifting and propelling the body forward in locomotion When most of the flexors and extensors of the leg are paralyzed, the foot hangs loose from the leg, the so-called flail foot (drop foot). Weakness of the flexor group (tibialis posterior, flexor digitorum longus and flexor hallucis longus) tends to favor a descent of the arch with consequent pronation or eversion. Weakness of the extensors causes toe drop and inversion or supination.

Paralysis of the calf muscles deprives the posterior pillar of the arch of its support, and the action of the flexors and extensors elevates the arch while the heel descends, so that a condition of hollow foot is produced

The Action of the Muscles as Abductors and Adductors. Lateral movements of the foot are comparatively weak. These movements are for maintenance of equilibrium and adaptation of the position of the foot to uneven surfaces. Three muscles act very distinctly as abductors; they are the peroneus longus, brevis and tertius Two act as distinct adductors, namely, the tibialis anterior and the tibialis posterior

The muscles of the calf act more as abductors than adductors, because the insertion of the Achilles tendon (tendo calcaneus, tendo achillis) is not directly behind the ankle joint but more to its outer side

When the foot is deformed in the position of inversion, as in clubfoot, the tibialis anterior and posterior are usually contracted, but when in the position of eversion, as in flatfoot, spasm of the peronei or calf muscles is frequent.

Plantar flexion of the foot is a far more powerful movement than extension. Flexion is associated with adduction or inversion and extension with abduction or eversion, hence it is that inversion is the position of strength, and eversion of weakness Feats of strength and agility cannot be performed by those who have markedly everted feet.

Detached Osteophytes These occur in persons of later middle age or senility who have had osteo-arthritis for years

Synovial Osteochondromatosis. There are numerous loose bodies from the synovial membrane.

Osteochondritis Dissecans. This condition usually begins between 10 and 19 years of age and probably represents a form of aseptic necrosis of subchondral bone. The loose piece of subchondral bone with its overlying hyaline cartilage may not be present in the joint as a true loose body and yet the patient may have considerable distress in the form of a dull aching pain. The roentgenogram of the intercondylar notch is often invaluable in demonstrating this lesion.

Osteochondral Fracture This type of loose body results from a fracture involving the joint surface whereby a loose fragment is displaced into the joint.

AFFECTIONS OF THE SOFT TISSUES. *Cysts and Adventitious Bursae* These sometimes appear about the ligaments of the knees and may cause pain and disability of the knee

Hypertrophic Infrapatellar Fat Pads These sometimes occur but are probably very rare. This condition may cause a locking or catching sensation as the fat pad is pinched between the articular surfaces of the femur and the tibia.

Intra-Articular Adhesions These sometimes limit the range of motion of the joint or may even cause a catching sensation but rarely a true locking

FRACTURES OF THE TIBIAL SPINE. These really are lesions of the cruciate ligaments A positive diagnosis can be made only by roentgenologic methods and especially by a roentgenogram of the intercondylar notch

RECURRENT DISLOCATION OF THE PATELLA. This lesion is much more often encountered in women than in men and is often on a congenital basis. The patient gives a history of acute episodes characterized by a sudden slipping and locking sensation with severe pain. The knee may remain locked in flexion If the patient is observant, she will state that the kneecap seems to be displaced to the lateral side of the knee and that she usually manipulates it back to its original position, whereupon the acute pain rapidly disappears. The knee after this episode becomes considerably swollen and may be moderately painful for 1 to 2 weeks

Ankylosis of the Knee Joint. The knee joint is of the hinge type but has a slight freedom of action in rotation and lateral mobility so that it is also a gliding joint.

In ankylosis of the knee rigid fixation in extension is more favorable to function, while flexion is less favorable However, slight flexion has an advantage since, by shortening, the foot has more room to pass forward along the ground

Contusion to the knee joint may produce synovitis, followed by adhesions and limitation of motion

Joint swelling of the knee or synovitis with local redness and heat associated with fever is an infectious process, not an injury. Trauma does not produce the symptoms of inflammation as does infection Synovitis of the knee, produced by a strain or sprain, causes swelling and distention of the joint but does not cause fever or a generally reddened, hot, painful joint

In either partial or complete ankylosis of the knee the nearer the motion can approach full extension the less the disability. Fifteen or 20 degrees of flexion, starting from full extension, permits most of the activities of the leg as a support and walking can be carried out with little mechanical interference (McBride).

Tumors and Swellings. Of the tumors in the region of the knee joint, lipoma is the commonest. Occasionally a sarcoma of one of the bones is met with, or a fibroma or sarcoma may originate in the synovial membrane.

Chronic swellings in the neighborhood of the knee joint, other than neoplasm, are commoner. Thus, in front of the joint, swellings are due to (1) *chronic bursitis prepatellaris*, (2) chronic bursitis pretibialis, or (3) bursitis behind the patellar

Peroneus Longus and Brevis. The patient tries to evert the foot against resistance. The tendons can be felt and usually seen (Fig. 6-65). (Sciatic nerve supply, L_5, S_1.)

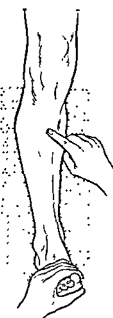

Fig 6-61 Tibialis anterior muscle. Lying on back or sitting, patient attempts to dorsiflex the toes against resistance The tendons can be seen and felt Nerve supply L_4, L_5, S_1 (sciatic nerve).

Fig 6-62. Extensor digitorum longus muscle. Lying on back or sitting, patient attempts to dorsiflex the toes against resistance The muscles can be seen and felt Nerve supply L_5, S_1 (sciatic nerve)

FIG 6-61 FIG 6-62

Small Muscles of Foot. The patient tries to make a cup of the sole of the foot (Fig. 6-66) (Sciatic nerve supply, S_1, S_2) *

Anterior Tibial Syndrome. The anterior tibial syndrome occurs chiefly in young men and consists of ischemic necrosis of the muscles of the anterior tibial

Fig 6-63 Extensor hallucis longus muscle. Lying on back or sitting, patient attempts to dorsiflex the great toe against resistance The tendon can be felt and seen Nerve supply L_5, S_1 (sciatic nerve)

Fig 6-64 Extensor digitorum brevis muscle Lying on the back or sitting, patient attempts to dorsiflex the great toe against resistance The muscle can be seen and felt Nerve supply S_1 (sciatic nerve)

Functional Testing of the Muscles of the Leg and Foot. *Gastrocnemius.* The patient in the prone position tries to plantar-flex the ankle joint against resistance. The muscle belly and tendon can be seen and felt (Fig. 6-58). (Sciatic nerve supply, S_1, S_2.)

Tibialis Posterior. The patient lies on the back and tries to invert the plantar-flexed foot against resistance. The tendon can be seen and felt (Fig. 6-59) (Sciatic nerve supply, L_4, L_5.)

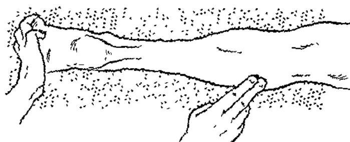

Fig. 6-58 Gastrocnemius muscle. Lying on belly or on side with legs extended, patient attempts against resistance to plantar-flex the ankle The muscle can be seen and felt. Nerve supply S_1, S_2 (sciatic nerve)

Fig 6-59. Tibialis posterior muscle Lying on back with legs extended and abducted, the foot plantar-flexed, patient attempts to invert the foot against resistance The tendon can be seen and felt Nerve supply L_4, L_5 (sciatic nerve).

Fig 6-60 Flexor digitorum, flexor hallucis longus muscles Lying on back, legs abducted and extended and the foot plantar-flexed, patient attempts to flex the terminal joints of the toe against slight resistance. The muscles can be felt Nerve supply S_1, S_2 (sciatic nerve)

Flexor Digitorum Longus, Flexor Hallucis Longus. The patient tries to flex the terminal joints of the toes against slight resistance The muscle bellies can be felt (Fig. 6-60). (Sciatic nerve supply, S_1, S_2.)

Tibialis Anterior The patient tries to dorsiflex the ankle against resistance. The muscle belly and its tendon can be seen and felt (Fig. 6-61). (Sciatic nerve supply, L_4, L_5, S_1.)

Extensor Digitorum Longus. The patient tries to dorsiflex the toes against resistance The tendons passing to the outer four toes can be seen and felt (Fig. 6-62). (Sciatic nerve supply, L_5, S_1.)

Extensor Hallucis Longus. The patient tries to dorsiflex the great toe against resistance. The tendon can be seen and felt (Fig. 6-63). (Sciatic nerve supply, L_5, S_1.)

Extensor Digitorum Brevis. The patient tries to dorsiflex the great toe against resistance. The muscle belly can be felt and often seen (Fig. 6-64). (Sciatic nerve

condition is worse when the patient is resting; then there is an uncontrollable desire to move the legs. Generally speaking, continuous paresthesia points to an organic lesion of the nervous system, while intermittent paresthesia of the type described in this syndrome points to a functional disorder possibly of vasomotor nature.

Massage has no effect, but getting up and walking about may give relief. The disagreeable sensation stops at once on chewing 1/100 grain of nitroglycerin.

Fat Legs and Edema (Lipedema). Those who have lipedema complain of enlargement of the limbs, aching distress in them, particularly during activity, and marked tenderness of the legs. The emotional reaction of patients to this syndrome varies from curiosity relative to its significance to marked evidence of anxiety and tension. In women who are desirous of maintaining a youthful appearance the emotional reactions to the fat legs may be considerable. There are insomnia, nervousness, tenseness, melancholia, anxiety and feelings of frustration. Such a woman is ashamed of her legs or feels that her large legs have ruined her life. These feelings and symptoms are understandable reactions to a disfigurement which is in conflict with the shapely legs of the model for hosiery advertisements. Understandable too is the wearing of long skirts to hide the legs, the avoidance of appearing in swimming suits, and the standing behind chairs at parties

Characteristically, there is symmetric bilateral enlargement of the buttocks and lower extremities which begins almost imperceptibly and progresses gradually. Progressive enlargement of the limbs is ordinarily associated with gain of weight, but evidence of obesity of the trunk, upper extremities, face and neck may be entirely absent, in some instances, there is generalized obesity. The enlargement of the limbs is accentuated by orthostatic activity, particularly in warm weather. Although rest in bed may cause some decrease in size of the legs, it will not cause the limbs to return to a normal size Recurring inflammations, such as are observed in lymphedema, are uniformly absent The feet are normal in size and configuration. There is moderate to great sensitiveness to digital pressure.

THE ANKLE

The ankle is a hinge joint and its motion is anteroposterior except in maximal extension, when a limited degree of lateral movement is possible The range of movement of the ankle is 80 degrees 20 degrees of flexion and 60 degrees of extension

The contour of the ankle is rather uniform, but this uniformity is easily destroyed by diseases and injuries The tibial malleoli form prominences with distinct hollows above and below them The sharp anterior edge of the tibia if followed distally leads to the tibialis anterior tendon On the medial (inner) side the malleolus is large and flat It is subcutaneous and can be readily palpated At its anterior edge is the commencement of the long saphenous vein which runs proximally and slightly back to reach the posterior edge of the tibia About 1½ inch (about 4 cm) distal and in front of the internal malleolus is the prominent tubercle of the scaphoid.

The external malleolus is small and somewhat pointed, and is placed a fingerbreadth distal and behind the level of the internal malleolus Proximal to the tip of the external malleolus is the fibula, which is subcutaneous and readily palpated The transverse line of the joint is level with the upper limit of the swell of the internal malleolus The ankle is covered in front and behind by tendons, most of which, especially in thin persons, can be felt and seen when their muscles are contracted

Posteriorly the tendo calcaneous (tendo achillis) is large and prominent. The posterior tibial artery can be felt pulsating midway between the tendo calcaneus and the internal malleolus The anterior tibial artery can be felt pulsating to the lateral (outer) side of the extensor hallucis longus.

Sprain of the Ankle. In what is usually called a sprain of the ankle the injury is not always confined to the ankle joint and its ligaments In many cases there is a

portion of the leg, with a lesion of the anterior tibial nerve The onset of symptoms is directly related to trauma or physical exertion involving strenuous use of the leg muscles. Unaccustomed exertion causes muscle trauma, which is followed by increased pressure within the anterior tibial region, impaired blood supply to the affected muscles, and ischemic necrosis The anterior tibial nerve is involved either by compression, in which case it recovers rapidly, or by ischemia, in which case the loss of function is permanent The symptoms are pain in the front of the leg fol-

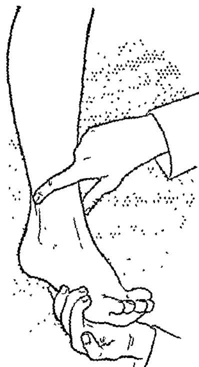

Fig 6-65 Peroneus longus and brevis muscles Lying on back with legs extended and abducted, patient attempts to evert the foot against resistance Tendons can be felt and seen Nerve supply L_5, S_1 (sciatic nerve)

Fig 6-66 Small muscles of sole of foot Lying on back with legs extended, patient attempts to cup the sole of the foot Nerve supply S_1, S_2 (sciatic nerve)

lowed by signs of inflammation over the pretibial muscles and inability to dorsiflex the foot and toes Important negative observations are normal action of the peroneal muscles and a minimal degree of foot drop If the syndrome is recognized early, rest alone may prevent irreversible damage to the muscles

Restless Legs (Anxietas Tibiarum, Leg Jitters). The symptoms are subjective and consist of paresthesias, a feeling of weakness in the legs and a sensation of cold in the feet. The paresthesias occur over the inner aspect of the legs, sometimes in the thighs but rarely in the feet. Characteristically, the crawling sensation develops only when the legs are still, most often after the patient retires for the night Sleep may be disturbed night after night for years with periods of improvement and exacerbation. The disease or syndrome occurs in two main forms. one is characterized mainly by paresthesia and is termed asthenia crurum paresthetica by Ekbom, and the other, in which pain predominates, is termed asthenia crurum dolorosa.

The paresthetic variety is an easily recognizable condition, probably closely related to acroparesthesia and nocturnal burning feet. The painful variety consists of mild to moderate aching localized in the same situations as the paresthesia The

necessitate more work for the long and short muscles and tend to cause foot tire and leg ache.

When all of the weight is borne on the ball of the foot, as in walking on tiptoe, it is called toe-to-toe walking. Toe-to-toe walking imparts greater elasticity and spring to the gait and results in less shock impact than heel-to-toe walking Because of the added elasticity and spring which is secured by toe-to-toe walking, it is used in running, and because it is more graceful, it is used in dancing.

The two tubercles of the calcaneous (os calcis) can be felt posteriorly and at the sides The external surface can be followed forward, but the internal is buried beneath the soft tissues Of the two tubercles on its undersurface the internal can be felt on the sole of the foot by firm pressure

The tubercle of the scaphoid (navicular) lies on the plantar rather than on the lateral aspect of the bone. It can be felt 1½ inches (about 4 cm.) below and in front of the internal malleolus. It is the landmark for the tarsal joints on the inner side of the foot The tibialis posterior muscle runs from it to the posterior edge of the internal malleolus.

The tuberosity of the fifth metatarsal bone is the large bony prominence 2½ inches (about 6 cm) below and in front of the external malleolus. It is the guide to the tarsal joints on the outside of the foot. The tendon of the peroneus brevis runs from it to the posterior edge of the external malleolus

ANKYLOSIS OF THE TOE JOINTS

Complete Ankylosis. Fixed ankylosis of the big toe at the metatarsophalangeal joint is termed hallux rigidus, this is the commonest site of complete ankylosis. This condition may arise as the result of osteoarthritic changes or from severe fracture extending into the joint It may also result from infection and occasionally from operations which involve the joint When ankylosis occurs, a very slight dorsiflexion is of advantage.

The middle phalangeal joint may also become rigidly ankylosed but does not have the importance of the metatarsophalangeal joint The lesser toes may be individually or collectively ankylosed If the metatarsophalangeal joints are fixed in a dorsiflexed position, there occurs a prominence to the ball of the foot so that the anterior arch is obliterated The condition is termed clawfoot

When the middle phalangeal joint becomes ankylosed in a flexed position, the metatarsophalangeal joint is usually dorsiflexed and the condition is termed hammer toe

Partial Ankylosis. Partial limitation of the ankle and tarsal joints is one of the commonest disabilities of the foot Particularly, the plantar flexion deformity is common because so frequently injuries of the leg or foot are treated with the foot in a splint which does not hold it to a right angle

The common causes of partial ankylosis of the toes are (1) contusions or sprains, (2) dislocations, (3) fractures in or near the joints, (4) continuous immobilization, (5) scar contracture, (6) suppuration and (7) rheumatic arthritis

When a toe is examined a considerable length of time after the healing of an injury, the amount of movement that was normal for the toe previous to injury is unknown except by comparison with the movements of the toes of the other foot. On account of the confinement of the toes within the shoe, there is a variation in the shape and motion of toes

ANATOMIC DERANGEMENTS AND FUNCTIONAL DISORDERS OF THE FOOT

Foot Imbalance. Children have one basic type of foot imbalance—*pes planus* The adolescent has two basic types—*pes planus* and *pes cavus*. The adult has both of these imbalances and, as the result, trouble may originate in the anterior arch.

Pes Planus (*Flatfoot*). A flat foot is characterized by inrolling or pronation of the foot and a depression or lowering of the longitudinal arch

tearing off of small fragments of bone; hence the name sprain fracture. Inasmuch as sprains are usually the consequences of lateral displacement, the resultant injury is frequently in the subastragaloid and sometimes in the *adjacent tarsal joints*. A sprain is frequently the result of an inversion, rather than of an eversion, of the foot because in eversion the plantar ligaments are so strong that the foot moves as a whole and the force is transmitted directly to the ankle and leg bones.

A sprain of the ankle is accompanied by pain, swelling and loss of function but there is no subcutaneous ecchymosis

Ankylosis of the Ankle Joint. The ankle joint is a hinge joint with flexion and extension A wide range of motion is provided by the tarsal joints. *The muscle relationship* between the ankle and tarsal joints is correlative.

The common causes of partial ankylosis are contusions, strains, sprains; fractures (*Pott's fracture*), dislocations, continuous immobilization, scar contractures, suppurations and rheumatic arthritis

When the foot cannot be brought to the right angle position, the toe drags as the foot advances Toe drag creates awkwardness and stumbling. Strength, security *and co-ordination are most affected, but quickness and endurance are also decreased* to a degree proportional to the extent of equinus. An individual who must walk on tiptoe has a noticeable deformity and limp

[illegible] the foot cannot

part [illegible]

stab [illegible]

affected so long as the foot can reach a right angle position

When the degree of abduction or pronation is limited to the midline, there is interference in shifting of the weight in taking a step. The gait in the presence of eversion is limited in smoothness and there may be loss of endurance In squatting or jumping there is need of abduction to permit complete dorsiflexion of the foot. Limitation of eversion, however, does not prohibit use of the foot for any particular activity When abduction and eversion are limited to the extent that the foot cannot be brought to the midline, the deformity and limp are obvious.

When the foot is everted and cannot be adducted, there is an increased strain on the arch, and endurance is affected The foot lacks the flexible inward rotation and the weight must therefore be borne mostly on the big toe in taking a step or while standing (McBride)

THE FOOT

The foot provides support for the weight of the body, acts as a lever to raise and to propel it into motion, and when the body is in motion, acts to prevent it from receiving sudden or unexpected jolts.

If standing is too prolonged, ligaments stretch and permit abnormal separation of the foot bones and induce a true foot strain The standing position in which the *foot points straight forward or in which* there is moderate outtoeing is the position in which locking of the bones of the foot is at its maximum and the ligaments are under the least strain.

With the body in motion the muscles play a more important role in supporting the foot than they do with the body at rest, because of the element of postural stability. The long muscles become more important as supports of the arches, since by maintaining the leg in balance over the foot, they prevent abnormal concentration *of weight* stresses on one part of the foot

In heel-to-toe walking, to be efficient, the foot points directly forward in the sagittal plane with each step or at least toes out only 20 to 30 degrees. The foot in the adducted position is, from a structural point of view, in a stronger position than that in which the foot is in the *neutral* or straight position. When the foot toes out more than 30 degrees, the loss of flexibility and interference with smooth action

normal range of dorsiflexion of the first metatarsal bone indicates a hypermobile first metatarsal segment. Callosities under the heads of metatarsals I, II and V and at times over the entire ball of the foot are frequently observed.

In the rigid flat foot the tendons of the peroneus longus and brevis are short and contracted. The lateral mobility of the foot is limited.

The roentgenogram may reveal a short first metatarsal with overdevelopment of the second metatarsal, a metatarsus varus primus with wide separation between metatarsals I and II, a hypermobile first metatarsal segment, or arthritic changes in the foot joints.

DIAGNOSIS. The diagnosis of pes planus is based on the foregoing symptoms and objective findings

Pes Cavus (*High-Arched Foot*). Pes cavus is often congenital but may occur as the result of muscle imbalance secondary to muscle paralysis, especially owing to infantile paralysis, when it is almost invariably due to weakness of the dorsal flexors of the toes and overaction of plantar flexors, plantar intrinsic muscles and heel tendon. Pes cavus also occurs in spastic paralysis due to overaction of muscles

SYMPTOMS. There is pain in the ball of the foot described as a feeling of walking on something hard under the ball of the foot There is tiring in the longitudinal arch of the foot, particularly across the dorsum, and cramping in the calf of the leg Backache is often present if anteroposterior balance is disturbed by a tilting of the pelvis downward and forward

There is less flexibility in the foot as a whole than in a normal or a flat foot.

EXAMINATION With the patient in the standing position, inspection will reveal that the longitudinal arch is abnormally high, the forepart of the foot is somewhat adducted, and the toes are in There may be the appearance of pronation owing to inward rolling of the foot at the ankle joint The line of transmitted weight falls toward the lateral side of the foot, which tends to roll it outward

When the patient sits, it is observed that the Achilles tendon is short, either actually or relatively, because of dropping of the forepart of the foot The ball of the foot is prominent and there is callus formation Tenderness is present over the contracted plantar fascia and over the heads of the metatarsal bones

DIAGNOSIS. The diagnosis of pes cavus is based on the presence of an abnormally high arch, shortening of the plantar fascia, prominence of the ball of the foot, and callus formation There is an absence of pronation, and there is shortening or at least functional shortening of the Achilles tendon Roentgenograms yield very little information

Descent of the Metatarsal Arch and Anterior Metatarsalgia. A depression of the metatarsal arch is associated with either pes planus or pes cavus Disturbances of the metatarsal arch may occur as a separate entity in women more than 30 years of age who have worn improperly fitting shoes

A depressed metatarsal arch is due to improper distribution of weight stresses over the foot as the result of pes planus, pes cavus and improper footwear. High-heeled, pointed, narrow-toed shoes displace the burden of weight-bearing on the metatarsal arch and limit the forepart of the foot and toes in their normal movements.

There is discomfort in the ball of the foot often amounting to acute, cramplike, burning pain in the second and fourth toes. There is loss of the normal dorsal convexity of the metatarsal arch The toes are flexed so that a hammer-toe position is assumed Callus formation often extends across the ball of the foot

Metatarsalgia (*Morton's Toe*) Anterior metatarsalgia represents an advanced form of a depressed metatarsal arch Anterior metatarsalgia is characterized by the sudden onset, while walking, of an acute burning pain in the fourth toe but at times in the second toe This pain is so severe that the shoe must be removed and the toes

ETIOLOGY. Flat feet may result from (1) deformities of the bone, (2) short Achilles tendon (tendo calcaneus, heel cord), (3) muscle inadequacy, (4) ill-fitting shoes and (5) knock knees, bowlegs and tibial torsion.

Deformities of the bones constitute a short metatarsal I, metatarsus varus primus, hypermobility of the first metatarsal segment, and accessory scaphoid, or prehallux, in addition to those resulting from trauma and infection which are so numerous as to be indescribable. The architecture of the foot may be deformed from fracture of bones and loss of the great toe

Hallux valgus develops by depriving the medial side of the foot of the supporting action of the great toe, allowing the foot to pronate, which encourages the descent of the longitudinal arch Fractures of the os calcis commonly cause a depression of the longitudinal arch

A short Achilles tendon prevents dorsiflexion of the foot and shifts the weight-bearing to the anterior part of the foot. The weight on the forepart of the foot causes downward and inward displacement of the subastragalar joint and descent of the longitudinal arch. The pull of a short Achilles tendon tends to displace the os calcis inward and to tilt the subastragalar joint downward and inward, which depresses the longitudinal arch of the foot

Flatfoot may be due to an inability of the muscles to maintain the leg in an approximately vertical plane over the foot. Weakness of the leg and foot muscles may result from illness, obesity or muscle paralysis A commoner cause of muscle weakness is prolonged standing, usually occupational

Shoes having high heels and inadequate length and width may cause foot imbalance. In such shoes the toes are crowded into the forepart of the shoes and thus the weight is borne on tiptoes

Normally the line of transmitted weight of the body passes approximately through the middle of the patella straight downward between metatarsals I and II In the presence of knock knee the line of weight-bearing is shifted through metatarsal I or medial to it With bowleg and tibial torsion the line of weight-bearing falls through metatarsal I or medial to it, just as it does in knock knee, and the weight-bearing thrust is on the medial side of the foot Excessive weight-bearing here rotates the medial side of the foot downward and inward at the subastragalar joint with eventual depression of the longitudinal arch.

SYMPTOMS The first symptom is a tired feeling in the longitudinal arch and the calf of the leg This tired feeling gradually increases in intensity and in time becomes a disabling pain The pain is localized in the region of the scaphoid bone and the subastragalar joint but may include the entire foot Cramping pain in the calf of the leg is often present Pain develops in the knee as the result of the shifting inward of the line of transmitted weight

A downward tilting of the front of the pelvis, accompanied by the secondary upward and forward tilting of the back of the pelvis which may result from extreme instances of inrolling of the feet, increases the work of the lumbar muscles and ligaments and is said to be responsible for the backache in pes planus.

EXAMINATION When making an examination for objective evidence of pes planus or flatfoot, request the patient to stand with the feet parallel and about 3 inches (about 8 cm) apart If there is flatfoot, the longitudinal arch is depressed. The foot is pronated so that the line of transmitted weight falls through metatarsal I or even medial to the inner border of the foot

The scaphoid bone and the internal malleolus are prominent owing to pronation or downward and inward rolling of the subastragalar joint. The great toe is short compared with the other toes. Prominence of the great toe with lateral projection and a broad, splayed-out forefoot are present in metatarsus varus primus.

Tenderness to palpation is usually present in the region of the scaphoid bone and the head of the astragalus and over the plantar surface of the middle cuneiform bone.

The range of dorsal flexion in the male foot with the knee extended and the foot held in mild adduction is 85 or 90 degrees, in the female foot, 90 degrees. An ab-

and the tip of the toe impinges on the ground, it is called mallet toe. This toe deformity gives remarkably little distress in most instances

Congenital hammer toe often involves the second or fifth toe; it is often a familial characteristic but may be observed when the foot is paralyzed.

In rare instances the deformed toe is affected by bursitis In mallet toe a sensitive callosity may form over the end of the toe in close proximity to the nail

Injuries to the Sesamoid Bones. The sesamoid bones of the foot are often irritated, injured, and occasionally fractured. Improper weight-bearing may cause a localized irritation of the sesamoid bones of the great toe joint. Proliferative changes may take place in the sesamoids which increase in size and become irregular in shape; exostoses may even be felt about the margins of such an irritated sesamoid Irritation of a sesamoid is characterized by local pain over the involved bone and tenderness at the same point

Affections of the Tarsal and Metatarsal Bones. ***Köhler's Disease of the Tarsal Scaphoid.*** Kohler's disease occurs in children between the ages of 4 and 7 years and is found more frequently in boys than in girls The cause is a degenerative bone condition which occurs in the young Trauma is a contributing causative factor. Necrotic changes in the cancellous bone with replacement fibrosis have been found.

There is localized pain over the scaphoid bone, aggravated by use and accompanied by a limp Objectively there is tenderness over the scaphoid bone and, at times, swelling Roentgenograms taken in the dorsoplantar and lateral planes show that the tarsal scaphoid is small, dense, often irregular, and narrow in its anteroposterior diameter.

March Foot. March foot is characterized by a painful swelling on the dorsum of the foot, often associated with a spontaneous fracture of one of the metatarsal bones, usually the second or third The condition follows long walks with excessive weight on the back

Interference with the blood supply with weakening of the bones has been suggested as a cause of march foot Extensive use of the forepart of the foot under adverse conditions is the most logical explanation of the condition

When spontaneous fracture occurs, there are periosteal proliferation, fracture of the involved metatarsal bone, and finally, as healing progresses, excess callus formation.

There is pain in the fore part of the foot. Walking is seriously interfered with or is impossible There is swelling over the dorsum of the foot with localized redness and pain There is an area tender to pressure over the distal part of the second or third metatarsal bone If fracture is present, it is impossible to bear weight on the foot After the lapse of a week or two, a roentgenogram will show a periosteal fuzziness at the site of the beginning fracture

Infraction of the Second Metatarsal Bone (*Freiberg's Disease*) This is an affection of the head of the second metatarsal bone occurring in adolescents and characterized by degenerative changes with pain in the metatarsophalangeal joint of the second toe. Trauma plays a contributing role in the causation of the condition

The head of the second metatarsal bone becomes distorted and irregular from degenerative changes There is an accompanying thickening of the shaft of the bone Pain is present over the head of the second metatarsal bone and walking is interfered with There are localized swelling and thickening of the metatarsophalangeal joint of the second toe The joint is tender to pressure and may show evidence of [illegible] plane show char-

[illegible] changes over the tuberosity of the os calcis at the attachment of the plantar fascia may develop into spurs or spurlike prominences Formerly calcaneal spurs were erroneously considered to be caused by a neisserian infection However, systemic infection, local irri-

massaged and manipulated to relieve the discomfort. Attacks of pain tend to become more and more frequent, and the duration more prolonged

The digital nerves come to lie in such a position that they are pressed on. There may or may not be a tumor present which increases the pressure on the nerve. The tumor often present in Morton's toe is either a neurofibroma or an angioneurofibroma The nerve pressed on in metatarsalgia is, as a rule, the fourth plantar nerve which is firmly held down against excursions of the toe by the short flexor of the fourth toe, producing conditions favorable to trauma.

Congenital Clubfoot. Congenital clubfoot occurs about once in each 1,000 births. A hereditary background is ascertained in 5 to 45 per cent of the cases. There are four deformities present in congenital clubfoot: (1) adduction of the forepart of the foot, (2) inversion of the hind part of the foot, (3) equinus and (4) tibial torsion Hart has stated that most children with a congenital clubfoot deformity treated within the first 6 months of life can obtain a functionally normal foot by nonoperative treatment

Hallux. Hallux Valgus (*Bunion*). Hallux valgus is characterized by lateral angulation of the great toe at the metatarsophalangeal joint and enlargement of the medial side of the head of the first metatarsal bone with the formation of a bony prominence which in time becomes covered by a bursal sac.

The basic cause of hallux valgus lies in a weakness of the architecture of the foot There is often a hypermobile first metatarsal segment and there are depressions of the longitudinal and metatarsal arches

Degrees of hallux valgus are commonly present without symptoms. Burning pain at the metatarsophalangeal joint of the great toe is common among those who have symptoms The pain is caused by pressure and irritation of the prominence

There is a lateral deviation of the great toe and the prominence on the medial side of the head of the first metatarsal, as stated, and often a hammer-toe deformity of the second toe is present Depression of the longitudinal arch due to the loss of support of the great toe is often present The metatarsal arch is often depressed and there is callus formation over the head of the second metatarsal bone The bursa over the prominence often becomes distended with fluid and inflamed and even infected, when it may break down with sinus formation

Hallux Varus. Hallux varus is a congenital deformity in which the great toe is smaller than normal and is held projected toward the medial side of the foot, it is usually associated with metatarsus varus.

Tailor's Bunion. A bunion over the tuberosity of the fifth metatarsal bone has been called a tailor's bunion because tailors often have this type of bunion owing to the position in which they sit while sewing. The condition is largely due to friction over the prominent tuberosity of the fifth metatarsal bone by the outer side of the shoe.

Hallux Rigidus (*Hallux Flexus*) Hallux rigidus involves the metatarsophalangeal joint of the great toe There is limitation of motion in this joint It may be associated with hallux valgus Ununited phalangeal fractures cause hallux flexus

"Stumping" trauma to the great toe joint and faulty weight-bearing cause this condition It is often a manifestation of arthritis

Stiffness preventing flexion in the great toe causes foot strain, and pain results on walking. The movements of dorsal and plantar flexion are limited. The toe may become fixed in plantar flexion A ridge of bone is palpable on the dorsum of the great toe joint Roentgenograms taken in the dorsoplantar and lateral planes will show narrowing of the joint space and hypertrophic changes in the head of the first metatarsal bone and the base of the first phalanx.

Hammer Toe. Hammer toe, often developing early in life, is a deformity of one or more toes characterized by acute plantar flexion and rigidity of the midphalangeal joint and extension at the distal phalangeal joint. If the distal joint remains straight

Club Nail (Onychogryposis). Club nail, or onychogryposis, is an excessive hypertrophy of the nail. The nail of the great toe is most frequently affected.

The twisted and thickened nail is generally found in the aged and is thought to be due to an irritation or pressure on the nail end, which in turn irritates the matrix, causing the nail to grow unevenly and at an increased rate. The dorsal layers grow more profusely than do the plantar layers; hence the end of the nail curls downward and the dorsal layers pile up to form a hornlike structure.

The treatment consists in clipping the nail short with heavy bone shears. This will give temporary relief, but the overgrowth of nail generally continues. It is often advisable to soften the nail with salicylic acid or calcium sulfide before clipping. When the club nail is sufficiently enlarged, it should be removed.

DISEASES COMMON TO THE AXIAL AND APPENDICULAR REGIONS AND AFFECTING LOCOMOTION

DISEASES AFFECTING MULTIPLE JOINTS AND LOCOMOTION

The disability in joint disease depends to some extent on the nature of the disease and the kind or class of joint affected Three classes of joints are described, namely, fibrous, cartilaginous and synovial.

Movements About Joints. Bones connected by the various types of joints are capable of the following different kinds of movement

Gliding movement is the simplest kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement.

Angular movement occurs only between the long bones, and by it the angle between the two bones is either increased or diminished It includes flexion, extension, abduction and adduction

Flexion is ventral bending, except at the knee joint, while in the four-footed position.

Extension is straightening out of bones of a joint, hence the reverse of flexion.

Abduction means to draw away from the middle line of the body.

Adduction means brought to, or nearer, the middle line of the body.

Both abduction and adduction have different meanings when used with reference to the fingers and toes In the hand the imaginary line is supposed to be drawn through the middle finger, and in the foot, through the second toe.

Circumduction is that form of motion which takes place between the head of a bone and its articular cavity when the bone is made to circumscribe a conical space by rotation around an imaginary axis, for instance swinging the arms or legs

Rotation is a form of movement in which a bone moves around a central axis, often an imaginary one, without undergoing any displacement from this axis No part of the body is capable of perfect rotation, like a wheel, for the simple reason that such motion would necessarily tear asunder all the vessels, nerves and muscles which unite it with other parts

Joint Pain. Pain is experienced when any of the sensitive structures of the joint are stimulated with a faradic or direct current, or by pinching, tearing, burning with a cautery or acid, cutting with a knife or chisel, or sticking with a needle. Thus the *structures of a joint are all sensitive* to acute injury.

A painful stimulation or injury of fascia, tendons and periosteum, according to McEwin, gives rise to pain felt at the corresponding site of injury distal to it

The stimuli which originate pain in traumatic lesions and in such derangements of a joint as occur in osteoarthritis are likely due to mechanical tearing and squeezing which stimulate the nerve endings and secondarily give rise to inflammatory edema which presses on nerve endings and exerts tension on the nerve networks. In infections of the joints, inflammatory edema and toxic or chemical irritants released as part of the inflammatory process are sufficient in themselves to cause joint pain Less is known about the mechanism of pain production in *periarticular painful conditions* such as the arthralgias and fibrositis

tation caused by faulty foot attitude, and acute or repeated trauma are etiologically important.

There is pain in the heel over the tuberosity of the os calcis aggravated by weight-bearing. There is a definite point of acute tenderness over the tuberosity of the os calcis. A lateral roentgenogram will show proliferative changes over the tuberosity of the os calcis and frequently, but not always, a true spur formation.

Calcaneal Apophysitis (*Epiphysitis of the Os Calcis*). The epiphysis of the os calcis lies at the tip of the heel and receives the attachment of the Achilles tendon It consequently may be partially separated in childhood by excessive strain exerted through the Achilles tendon, and symptoms may develop which resemble apophysitis Apophysitis represents a true degenerative affection involving the epiphysis. It occurs most often in boys between the ages of 10 and 15 years.

The etiology of apophysitis is unknown It may result from (1) direct trauma or strain from the attachment of the powerful heel tendon; (2) circulatory or nutritional disturbances of the epiphysis, probably secondary to trauma or (3) systemic infections

The first symptom is usually a slight limp which is followed by definite pain localizing on the posterior aspect of the os calcis at the tip of the heel. An area of tenderness over the tip of the heel may be elicited by the lateral palpation of the heel with the index finger and thumb Usually the line of tenderness to pressure follows the outline of the calcaneal epiphysis There is, at times, some swelling of the lateral and medial aspects of the heel and, in cases of long standing, edema may be present. A roentgenogram taken in the lateral plane will show the epiphysis to be irregular and segmented with areas of increased density

Tenosynovitis of the Achilles Tendon. This condition is similar to tenosynovitis involving any tendon sheath The condition is characterized by local pain, swelling and redness over the Achilles tendon and crepitation over the tendon on movement.

Bursitis. The bursa most commonly involved is the retrocalcaneal bursa, which lies between the os calcis and the Achilles tendon Inflammation of this bursa is characterized by local pain, tenderness, and swelling The swelling, when present, is localized on the sides of the Achilles tendon Local periostitis with proliferative changes and irregular spur formation on the posterior surface of the os calcis are occasionally found associated with inflammation of this bursa and may be the cause of the bursitis If the bursitis does not subside under conservative measures, the bursa should be excised

Friction of the heel counter of the shoe may cause bursitis of the superficial calcaneal bursa which lies between Achilles tendon and the skin. Such a superficial bursitis can usually be relieved by the application of heat and protecting the area by an adhesive strapping

AFFECTIONS OF THE NAILS

Ingrowing Toenail (Onychocryptosis—Onychia) Onychocryptosis is an acute inflammatory reaction, often frank infection, of the soft tissues at the corner of the nail of a toe. The nail of the great toe is most often involved.

On observation of the stance of the foot in individuals complaining of ingrowing toenails, faulty foot balance will usually be found. Pointed shoes which make pressure on the nail of the great toe, careless and improper trimming of the nails, and excessive width and abnormal convexity of the nail result in local irritation and may eventually cause an ingrowing nail.

Pain, tenderness, swelling and redness at the corner and along the lateral margin of the nail characterize the affection Frequently there is frank infection of the involved area with pus formation, subsequent to which the skin breaks down and a discharging area covered with sluggish granulations develops.

coccus The bacteria may reach the synovial tissue by hematogenous dissemination, invade the joint by direct extension from a suppurative process in adjacent bone, such as osteomyelitis, or they may be introduced into the joint cavity by a penetrating wound.

The synovial tissue is hyperemic, swollen, thickened and infiltrated If suppuration continues for several weeks, the result is ulceration and irreparable destruction of the articular cartilage When there is severe damage of the cartilage, ankylosis results. Abscesses may form in the marrow of the subchondral bone The soft periarticular structures often become acutely inflamed

SYMPTOMS The onset is often sudden with fever, chills, sweats, malaise and anorexia. The joint is tender, red, warm, swollen and painful. Its capsule is distended by effusion, and the adjacent muscles are in spasm Tenosynovitis and bursitis may be present Commonly the hip, knee, elbow or shoulder is affected although no joint is exempt It is rare that more than one or two joints are affected. In some cases the systemic disease may be so severe and the arthritis so mild that the joint infection is not noticed In others the arthritis may be unaccompanied by constitutional signs, and the probable primary focus of infection remains obscure.

EXAMINATION The joint or joints are red, swollen and tender. There is a definite leukocytosis with a rise in the percentage of polymorphonuclear cells. The erythrocyte sedimentation rate is elevated Blood culture will often reveal the causative microorganism before chemotherapy The synovial fluid is cloudy or frankly purulent and the leukocytes may number more than 100,000 per cubic millimeter with more than 90 per cent polymorphonuclear cells. On bacteriologic examination (both smear and culture) of aspirated synovial fluid the organism causing the arthritis can usually be demonstrated

After the tenth day, long after the disease should have been diagnosed, roent-
[illegible] ment has not been effective, roentgeno-
[illegible] stration of the extent of damage to the

DIAGNOSIS Recovery of the organism from synovial fluid by smear or culture proves the diagnosis. Acute monarthritis of abrupt onset, a red, warm, swollen, exquisitely painful and tender joint, associated with fever, leukocytosis and rapid sedimentation rate, is characteristic of suppurative arthritis

The prognosis as to life is generally determined by the nature of the systemic disease If correct therapy, and this depends on the nature of the infection, is started within the first week of infection, the prognosis is better than when treatment is started later

2 ***Meningococcal Arthritis.*** The incidence of articular complication during the course of epidemics of meningococcal meningitis varies from 2 to 20 per cent.

There are two general types of joint symptoms associated with epidemic meningitis The first type appears during the first few days of the disease, when there may be a transient multiple synovitis which resolves spontaneously without progressing
[illegible]

affected, any other synovial joint may, however, be involved

The joint on examination is acutely inflamed and distended with effusion

A diagnosis of meningococcal arthritis can be proved only by recovery of the organism from the joint fluid The general prognosis is not significantly influenced by the arthritis The bacteremia and arthritis usually respond satisfactorily to sulfonamide compounds (orally) or penicillin (intramuscularly).

3 ***Gonococcal Arthritis.*** Gonococcal arthritis results from a spread of the organisms from the primary focus in the urogenital tract through the lymphatics and blood stream to the synovial tissue. Arthritis usually appears within 10 to 30

The rapidity with which swelling of a joint takes place in some instances seems to determine the intensity of the symptoms This is not borne out in all instances by clinical observation, for a knee joint affected by that strange condition known as intermittent hydrops may swell rapidly and the swelling is not accompanied by pain. Those swellings which appear rapidly and are acutely painful are likely to be associated with more intense inflammation than other swellings. It is well, therefore, to know that swelling due to edema of tissue is painless in the absence of an *inflammation of the joint structures*

Referred pain may be felt in the joints from visceral disease, for example, shoulder pain in coronary artery disease, and, conversely, pain suggestive of visceral disease may be referred from skeletal lesions Pain arising in one joint may be felt in another, for instance, the pain referred to the knee in arthritis of the hip.

The tendency of *emotional shocks* and *stresses* to be followed by exacerbations of symptoms may occur in those who have rheumatoid arthritis The etiology of the arthralgias complained of by psychoneurotic patients is obscure.

POLYARTHRITIS

Various classifications of arthritis, comprising an enumeration of the groups of arthropathies, have been published The groups of arthritis which usually are included are as follows (1) infective, (2) traumatic, (3) joint diseases secondary to peripheral vascular disease, (4) joint disease secondary to blood dyscrasias, (5) allergic arthritis, (6) joint diseases of metabolic origin, (7) neuropathy secondary to disturbances of innervation or psychic control, (8) static or mechanical abnormality—loose bodies in the joint, (9) diseases of unknown or uncertain causes and (10) new growths.

Infective Arthritis. This group includes all forms of arthritis in which a bacterial or a viral etiology is demonstrated There are two groups of infective arthritis (1) the primary specific infection of the joint, which is characterized by bacterial invasion of the joint from without, (2) the secondary specific infection of the joint, which occurs from within although the bacteria may not be demonstrated

The primary specific infection is proved by bacteriologic study, and the bacteria are likewise demonstrated in the joint The bacteria have been carried to the joint by the blood stream The microorganisms which may thus cause joint disease are (1) staphylococci, (2) streptococci, (3) pneumococci, (4) meningococci, (5) gonococci, (6) tubercle bacilli, (7) *Brucella melitensis* (malta fever, brucellosis), (8) *Klebsiella granulomatis* (granuloma inguinale) and (9) *Treponema pallidum* (syphilis)

The secondary infective arthritis, in which the bacteria may or may not be demonstrated in the joint but in which arthralgic or arthritic manifestations accompany the primary disease are (1) scarlet fever, (2) samonellosis, (3) coccidioidal arthritis These arthropathies are considered with description of the primary disease elsewhere in this book.

The systemic diseases in which a filtrable virus is the causative agent, and in which arthralgia and joint changes are present, are dengue fever, measles, mumps, chickenpox, smallpox and Reiter's disease The joint diseases caused by the organisms or virus of dengue, measles, mumps, chickenpox and smallpox are mentioned in descriptions of these diseases. Reiter's disease is discussed in the portion of the text on infective arthritis.

The arthritides caused by the staphylococci, streptococci, pneumococci, gonococci and meningococci are often referred to collectively as *acute pyogenic arthritis*. Acute pneumococcal arthritis, though rare, may occur during the course of convalescence from pneumococcal pneumonia.

1. ***Staphylococcal and Streptococcal Arthritis.*** More than one half of the pyogenic arthritides are caused by the staphylococcus and the hemolytic strepto-

expressed from a sinus. It may be demonstrated by smear or recovered by culture or after inoculation of suitable material into guinea pigs.

DIAGNOSIS. The diagnosis is established by demonstration of the tubercle bacilli in the synovial fluid. A positive reaction to the tuberculin test is only suggestive evidence of tuberculous arthritis. A negative reaction is strong evidence against the diagnosis. A presumptive diagnosis can be made by the roentgenologist.

5. ***Brucellosis*** (*Malta Fever*). Brucellosis is not a common disease of the bone and rarely affects the joints Approximately half of the patients who have brucellosis experience arthralgia or myalgia, although only 10 per cent emphasize bone or joint pains as their chief complaint, and in but a fraction of this group are there objective signs of bone involvement. Permanent joint damage is rarely a result of brucellar infection (see Chapter 17)

There are no pathognomonic clinical features of the systemic infection or the joint involvement A positive culture of blood or synovial fluid is conclusive, but the former is obtained in only 1 of 4 cases and the latter even more rarely. An agglutination test, a complement fixation test, a bactericidal test, a skin test and an opsonocytophagic test have been developed but are difficult technically and of limited value because of false negative as well as false positive reactions. No single one of these tests is diagnostic. A positive culture from tissues is diagnostic.

The duration of brucellosis is variable and may be protracted. About 3 to 4 per cent of patients succumb to the infection. The arthritis does not influence the prognosis significantly It is usually mild and rarely results in permanent deformity. The disease is self-limited and subject to spontaneous remissions

6. **Syphilitic Arthritis.** The reported incidence of syphilitic disease of the joints decreases as the precision of diagnosis of joint disease increases

Arthritis occurs in the course of both congenital and acquired syphilis In the acquired type it may be due either to direct spirochetal infection of the joints or to neurogenic changes (Charcot's joints) secondary to tabes. The latter constitutes about half of the cases in the acquired group.

Generalized aching of the "bones" may be present during the height of the early systemic reaction in acquired syphilis

from 8 to 16 years of age a symmetric, painless synovitis is the commonest form of syphilitic arthritis (Clutton's joints) Interstitial keratitis is often associated The knees are most commonly affected There is bilateral effusion without redness and with only slight pain, tenderness or warmth

A monarticular gummatous arthritis may occur in late tertiary syphilis, congenital or acquired A gumma may arise in bone and extend into an adjacent joint, or it may originate in the synovia or other soft articular or periarticular structures. Swelling with little or no pain and without stiffness, local heat or muscle spasm is characteristic Bone destruction with osteolytic areas is frequently revealed by roentgenograms Response to antisyphilitic therapy is the rule

In those who have a Charcot joint as the result of neurosyphilis the reaction to serologic tests of blood and spinal fluid may be negative Diagnosis is based on the neurologic signs of tabes A Charcot joint also results from syringomyelia. Antisyphilitic therapy is ineffective

The diagnosis is proved by positive findings on biopsy of synovial or juxta-articular tissue A presumptive diagnosis is made on the presence of (1) positive serologic reaction, (2) other stigmas of congenital or acquired syphilis, (3) response to penicillin therapy or (4) characteristic changes in the bones seen in roentgenograms.

Reiter's Disease. Reiter's disease, a secondary specific infection, is due to a filtrable virus, a pleuropneumonic organism. This is a rare form of acute arthritis

days after the initial infection. However, it is said that months to years may intervene between the urethritis and the arthritis.

The onset of symptoms is sudden with fever, chills, and joint pains The constitutional symptoms are not severe enough to direct the attention away from the joint. The joint pains are those of an acute migratory polyarthritis, and often it is from a few days to a week before the localization becomes monarticular.

On examination in the period of the migratory joint pains, there are no definite findings except, usually, an active gonorrhea. As soon as there is localization to one joint, tenosynovitis is present Tenosynovitis occurs more frequently than arthritis, *particularly when the wrists or small joints of the hands or feet are affected.* There are leukocytosis and accelerated sedimentation rate.

Cultures of exudate and synovial fluid yield positive results more frequently than do smears Occasionally, however, the smear is positive and the culture is negative.

The reaction to the gonococcus complement fixation test becomes positive within 10 to 30 days after the onset of the urethritis in 9 of each 10 who have the disease Chemotherapy apparently does not affect the specificity of the test if arthritis has supervened. This test alone does not prove the presence or the absence of gonococcal arthritis. There are [illegible] gonococcal arthritis which distinguish [illegible]

The diagnosis of gonococcal a[illegible] the gonococcus by culture or smear of the synovial fluid Helpful diagnostic points are history of exposure and a characteristic clinical course of the disease. A positive reaction to the complement fixation test and recovery or improvement with penicillin or sulfonamide therapy are only presumptive diagnostic evidence.

4. ***Tuberculous Arthritis.*** About 1 of each 25 who have tuberculous infections have skeletal involvement. A tuberculous spondylitis is the most serious of the bone and joint infections (see tuberculous spondylitis, p. 281).

Tuberculosis of the peripheral joints may result either from direct bacillary invasion of the synovial tissue (tuberculous synovitis) or from penetration into the joint by tuberculous tissue from adjacent diseased bone. The formation of granulation tissue separates the articular cartilage Caseation, abscess and sinus formation may result

SYMPTOMS. In the peripheral joints there is an effusion into the joint. There are no signs of acute inflammation. Articular pain and tenderness are absent until late in the course of the disease. In tuberculous arthritis muscular atrophy is relatively early and prominent.

The commonest complication is usually the primary pulmonary infection. Abscess formation in the paravertebral region or in the vertebral bodies when the spinal [illegible] affected, and in the bone or periarticular soft structures when a peripheral [illegible] plegia may occur It seems that tuberculous bone and joint disease is a common cause of secondary amyloidosis

Tuberculous arthritis follows a protracted course of progressive destruction of bone and articular structures lasting several years Recovery of normal joint function is rare. In no other type of arthritis is the mortality rate so high as in tuberculosis of the spinal column.

EXAMINATION. The involved joint is swollen. The doughy feeling and swelling are due chiefly to edema and infiltration of the synovial tissue Redness of the joint is absent in the advanced stages unless the joint is secondarily infected following aspiration of fluid.

The total and differential leukocyte counts are usually normal The erythrocyte sedimentation rate is elevated. On bacteriologic study the tubercle bacillus will be found in the synovial fluid, synovial tissue or the pus aspirated from an abscess or

ness. Limitation of motion is due to the pain of inflamed joint structures and the associated muscle spasm A distention of the joint cavity may produce but little pain.

The diagnosis of acute traumatic synovitis is usually obvious from the history, the symptoms and the examination Aspiration of the joint is not routinely practiced, but in some instances it may be the surest and sometimes the only way of detecting fluid in the synovial cavity, and it serves the added advantage of revealing the kind of fluid present. Microscopic and bacteriologic investigation of the fluid is often useful and important diagnostically.

Diseases of the Joints Due to Circulatory Disturbances. *Diseases Secondary to Peripheral Vascular Disease.* *Aseptic necrosis of bone and joint* may occur secondarily to an infarct or other localized loss of arterial blood supply to bone adjacent to the joint In some instances there is an intra-articular fracture or a dislocation Aseptic necrosis results in pronounced irregularity in the contour of the articular surface with secondary degenerative joint disease.

Aseptic necrosis never eventuates if full restoration of the contours of the intra-articular surfaces occurs; it therefore differs from traumatic aseptic necrosis in that under favorable conditions restoration of normal articular contours may be expected in this disease

Joint disease and osteomyelitis occur secondarily to disturbances of blood flow during the progress of Raynaud's disease, scleroderma, thromboangiitis obliterans (Buerger's disease), ergotism and periarteritis nodosa

Disease Secondary to Blood Dyscrasias. Hemorrhage into a joint or joints of the extremities is a common manifestation of *hemophilia.* The joint becomes swollen, painful and stiff from intra-articular bleeding. The hemorrhage into the joint may be slight, or so great that pain and swelling continue for weeks Once a joint has been affected, it is likely to be affected again and again After repeated small hemorrhages or a large hemorrhage into a joint has occurred, the joint ultimately becomes ankylosed. One or more deformed ankylosed joints are present in practically every hemophiliac who has reached adulthood

Evidence of increased coagulation time of the blood in association with roentgenologic findings of atrophy of bone and periosteal thickening is sufficient for diagnosis. Pseudohemophilia causes the same sort of joint symptoms.

Allergic Arthritis. Experimental work indicates that there are true allergic forms of arthritis such as those observed during serum sickness and possibly sequential to the administration of drugs, particularly sulfonamide compounds and penicillin The opinion is abroad that sensitivity to foods may cause transient or permanent joint changes, but proof is lacking True allergic arthritis, aside from serum sickness, is rare, the diagnosis should be made with caution

Criep differentiated five types of allergic arthropathies. (1) certain instances of chronic arthritis which are thought to be due to bacterial allergy, (2) articular swelling resulting from sensitivity to a foreign serum or to a drug, (3) certain intermittent hydrarthroses, (4) some instances of Henoch's purpura associated with articular swelling and pain and (5) certain instances of acute transient paroxysmal articular involvement of joints characterized by pain, swelling and limitation of motion

The mechanism of production of symptoms is probably the same as that in urticaria or angioneurotic edema, the shock tissue is the synovial membrane of the joint instead of the skin

Hench has repeatedly stated in his publications that he has not been able to diagnose chronic allergic arthritis.

Intermittent Hydrarthrosis. Intermittent hydrarthrosis may be a manifestation of various joint diseases or of early rheumatoid arthritis The condition often affects the knees bilaterally. In some instances intermittent hydrarthrosis may be allergic in origin.

which is said to be limited to men. It causes mild to moderate constitutional reactions In size this organism stands midway between viruses and rickettsiae.

There is a triad of symptoms; namely, (1) acute polyarthritis, (2) urethral discharge and (3) conjunctivitis The onset is acute and the arthritis, the conjunctivitis or the urethral discharge may come first. There may be fever.

On examination one or more joints, usually of the hands, are red, swollen and moderately tender The urethral discharge may be mild or profuse and is negative for gonococci The conjunctivae are congested and often painful Conjunctival smears and cultures are negative for gonococci. The arthritis lasts for weeks or months and tends to recur.

The diagnosis is made by a process of elimination. The disease is self-limited. Rheumatoid arthritis is to be differentiated

Arthritis Due to Infection by Higher Animal Parasites. Generally the joints seem to be immune from invasion by animal parasites. If joints are affected from parasitic infestations, it is secondarily as the result of a sensitization to a toxin elaborated by the parasite, as has been suggested by Rappaport in a discussion of intestinal amebiasis

Traumatic Arthritis. The term traumatic arthritis applies to various injuries in and about the joints Traumatic arthritis may be caused by trauma applied extrinsically or intrinsically to the joint. It may be manifested either acutely or chronically

Acute extrinsic arthritis is often caused by a single *extrinsic* cause; for instance, the joint is struck a single blow which injures the intra-articular surface of the joint. However, acute joint symptoms are manifested if the structures about the joint are so injured as to result in, for example, a traumatic synovitis. In the absence of an *injury acute fibrositis, myositis, bursitis and tendinitis may occur spontaneously* and may be attributed to injury when there has been none

Often as a result of occupational or recreational repeated trauma chronic arthritis arises. It is not always possible to distinguish this type from some forms of degenerative joint disease such as osteoarthritis As in acute traumatic arthritis, it may be difficult to know whether a chronic joint disease is caused from chronic, spontaneously occurring fibrositis, myositis, bursitis and tendinitis or from trauma

Intrinsic injury of a joint usually causes a chronic disability Acute traumatic synovitis, however, may be due to sprains, strains, or fractures into a joint

Chronic traumatic arthritis may be caused by repeated or continuous minor trauma such as occurs as a result of faulty body mechanics, for instance postural scoliosis or flat feet This type is indistinguishable from osteoarthritis. Chronic traumatic arthritis may originate from avascular necrosis or from loose bodies (joint mice)

An accumulation of fluid in the joint cavity (hydrops, hydrarthrosis) is one of the first symptoms in the joint characteristic of synovitis The presence of fluid in the joint is manifested by pain, swelling, obliteration of the normal bony landmarks of the joint, and a sense of fluctuation on palpation The same reaction may occur in a mild degree when normal joints which have been immobilized for some time are first used

In the knee the fluid lifts the patella from its normal contact with the femur, an effect which can often be demonstrated by lightly punching the patella against the femur, producing an audible or palpable tap

In the hip and shoulder, swelling of the joint may be obscured by the overlying muscle However, a comparison in size with the opposite side reveals the degree of swelling present.

In all forms of acute traumatic synovitis the pain is severe. The intensity and distribution of the pain are enhanced by associated lesions of bone, ligament or tendon. The involvement of these additional structures is detectable by local tender-

ciency, leukemia, polycythemia vera and pernicious anemia. The serum uric acid is constantly elevated in chronic gout.

Therapeutic Test. Colchicine, if given promptly and in sufficient doses, will usually relieve the acute manifestations of gouty arthritis. Other forms of arthritis are unaffected by colchicine.

Neuropathic Arthritis. Joints atrophy when their nerve supply is badly deranged or discontinued. A neurotrophic joint disorder may be secondary to tabes dorsalis, syringomyelia, nerve injuries or leprosy. Hysterical and psychogenic disturbances also cause joint dysfunction.

In syringomyelia and in tabes, disturbances of joints are common Spontaneous fracture may occur from increased fragility. In the Morvan type of syringomyelia there may be gradual disintegration of a fingertip similar to that which occurs in leprosy and in Raynaud's disease.

A perforating ulcer of the leg or foot caused by tabes involves, at first, the soft parts; later on it may cause destruction of the underlying bone.

Charcot's Joint. The pathogenesis of Charcot's joint is not understood However, it is thought that this disorder is a rapidly developing degenerative process in joints lacking the protection of pain and position sense and hence used in an awkward and traumatizing manner

The onset may be gradual or sudden, and the course progressive or stationary One large joint of the lower extremities is usually affected by a painless enlargement and hypermobility. Occasionally, but rarely, the process is multi-articular and symmetric.

The flail joint is enlarged and deformed, and can be painlessly hyperflexed, extended and rotated in several directions. Warmth, redness and tenderness are absent

The diagnosis is made clinically on the basis of a neurologic examination in association with history and complaint. On roentgenologic examination there are usually destructive and productive bone changes with pathologic fractures, disintegration and disorganization of the joint.

Psychogenic Arthropathy. There are functional derangements of joints, without structural change, considered to be psychogenic The hysteric joint belongs in this group Recently considerable emphasis has been placed on what some call psychogenic rheumatism Some observers have believed that these psychogenic conditions, when of long standing, may result in true organic changes.

Psychoneurotic individuals in emotional conflict caused by psychic trauma, fear, anxiety, apprehension or sorrow may experience arthralgia, muscle and tendon aches, stiffness, interference with joint motion and other rheumatic symptoms which resemble arthritis or fibrositis

On examination by physical means there is absence of joint changes. Roentgenologic examination and laboratory observations reveal that organic health is good

In some instances, if a psychoneurosis is present, bizarre deformities which do not conform to anatomic changes are helpful diagnostic features It is difficult to differentiate psychogenic rheumatism from fibrositis In psychogenic rheumatism, however, there is a lack of consistent localization of symptoms, a lack of benefit from analgesics, heat and physical therapy, and there is failure to improve in a warm atmosphere and after mild exercise.

The Static Influences on Joints. An extremity is a static unit, and disturbance in one part of this unit will secondarily affect other parts. This static factor is symptomatically important in any joint disease.

In this connection two interesting changes that are met with about the joints may be mentioned, although they are easily recognized, the beginner may be puzzled

Suddenly, without prodromes, the knees feel stiff. The patient observes that the joints are swollen. There may or may not be pain. After varying intervals the swelling disappears, to recur weeks or months later. Several such attacks may occur without leaving any disability.

The general condition is good. Rarely are there other manifestations of the allergic state

There are no definite diagnostic criteria. The knees are swollen or distended with fluid. The diagnosis is made with caution. It seems, however, that intermittent hydrarthrosis may exist as a separate disease entity.

Joint Diseases of Metabolic Origin. *Gout and Gouty Arthritis.* In gout there is a concomitant disturbance of purine metabolism, and the disease is spoken of as being a metabolic arthritis. The definite etiology is not known. The disease is characterized by (1) often a family history of gout, (2) acute attacks of arthritis with freedom from joint symptoms between attacks unless chronic deforming changes have developed, (3) increased concentration of uric acid in serum and other body fluids, (4) deposition of sodium urate crystals in articular, periarticular and subcutaneous tissues and often uric acid stones in the urinary tract and (5) degenerative changes in the vessels of the kidneys, heart and brain as the disease advances.

At least 9 of every 10 patients who have gout are men more than 30 years of age. The disease occurs in all races, nationalities and social levels irrespective of their manner of living. Excessive ingestion of purine foods or alcohol may provoke an attack of gouty arthritis in those possessing a gouty diathesis but does not cause this error in metabolism Likewise surgical operations, dietary indiscretions, emotional stress, administration of crude liver extract, thiamine, dehydrocholic acid (Decholin) and mercurial diuretics may precipitate an acute attack

SYMPTOMS OF ACUTE GOUT. Within a period of a few hours the affected joint or joints become red, warm, swollen, tender to touch and acutely painful when moved. Weight-bearing is often impossible when the affected joint is in a lower extremity; for instance when the metatarsophalangeal joint of the great toe is affected. The metatarsophalangeal joint of the great toe is affected in about half of the patients, but other toes or joints of the feet, ankles, knees, hands, wrists or elbows may be involved. A moderate fever, leukocytosis and an increased sedimentation rate may be present. The arthritis may be monarticular, or migratory and polyarticular. Joint synovitis with effusion and acute bursitis are often associated. Specific treatment during the attack ameliorates the symptoms within a few days, otherwise, severe symptoms may last for several days or even weeks, until the disease is far advanced. After the acute attack the joint is free of symptoms until the next acute attack. Finally the joints are so injured by repeated attacks that chronic joint disease consisting of swelling, pain, partial or complete ankylosis is present

EXAMINATION. In addition to the tender, red, swollen joint, uric acid tophi may be present. They occur most often about the margin of the ears and less often in the olecranon region and around joints of the hands and feet. If a tophus is suspected, its contents should be removed and examined microscopically for needle-like crystals or chemically by means of the murexide test.

In chronic gout the joints may be found to be in various states of dilapidation; these joints are the source of great agony and total disability.

During the earlier stages or years of the disease the joints may appear normal on roentgenologic examination. As attacks recur, osseous tophi are observed as punched-out regions in the bones of the fingers or, more often, in the bones of the feet.

DIAGNOSIS. The diagnosis is based on the characteristics of the disease as enumerated.

The serum uric acid is increased during the acute attacks. Nongouty conditions which may be associated with an increase in serum uric acid include renal insuffi-

Rheumatic Diseases lists the theories of etiology as follows: (1) an infectious disease, (2) a metabolic disease, (3) a disease with an endocrinologic basis, (4) a disease of the peripheral circulatory apparatus, (5) a disease of the nervous system, (6) a psychogenic disease and (7) a disease of hypersensitivity. Data available now strongly suggest that rheumatoid arthritis belongs to those diseases arising from chronic anaphylaxis or hypersensitivity.

Rheumatoid arthritis is a systemic disorder. The disease affects primarily the interfibrillar substance of connective tissue. This substance is a colloidal, jelly-like material existing in the interstices between cells and fibers of mesenchymal origin. This substance is often termed collagen, and the diseases resulting from disturbances in this substance, collagen diseases

Articular lesions consist of a thickening of the synovial lining. As the disease progresses, the articular cartilage is softer, contains larger ulcerations, and connective tissue appears in the subchondral marrow spaces. The cartilage in time may be destroyed and ankylosis may occur. The cortex of the adjoining bones becomes thin and porous

The *subcutaneous nodules* of rheumatoid arthritis are a characteristic pathologic lesion of the disease. Exudation of plasma and blood cellular constituents is a prominent feature of *rheumatic fever nodules*, which contain, in addition, small focal regions resembling Aschoff bodies In the nodules of rheumatoid arthritis proliferation and degeneration predominate, Aschoff-like nodules are rare, and exudation is not a prominent feature. The blood vessels in these nodules are affected by perivascular infiltrations advancing to diffuse inflammation and degeneration of the entire vessel wall Thrombosis may be present

SYMPTOMS The first symptoms often are fatigue, to the point of exhaustion, lassitude, muscular stiffness, loss of weight and general debility. One or more joints slowly become swollen and painful, and function is hampered. The symptoms may commence with repeated mild attacks of polyarthritis accompanied by pain, swelling and redness of the affected joints, slight fever and tachycardia The joints of the hands usually are affected first. When the feet are affected, the foot pain is most severe after inactivity The pain may be somewhat relieved by activity; this is in contrast to the pain of flat feet, which is relieved by rest and made worse by activity

There are some patients in whom rheumatoid arthritis commenced with an acute polyarthritis, high fever and sweats. The polyarthritis advances rapidly and quickly reduces the patients to semi-invalidism or invalidism within a period of weeks

In almost all instances of rheumatoid arthritis the smaller joints of the hands, particularly the proximal interphalangeal joints of the fingers, are likely to be most severely affected

EXAMINATION A rheumatoid joint is swollen and there are pain and limitation of movement Owing to thickening of the periarticular tissues about the joint and the atrophy of the muscles proximal and distal to it, the joint presents a spindle-shaped appearance There is rarely much fluid in one of these joints. The adjacent bursae and tendon sheaths are frequently involved and swollen.

The muscles about a joint are antagonists The stronger of the antagonists, the flexors, exert more force on the joint, therefore the joint is often found in a flexion contracture. Flexion contractures are likely to be particularly apparent in the hands, wrists, knees, elbows and toes, but almost every joint in the body may be involved In cases of advanced disease fibrous and bony ankylosis may occur, accompanied by subluxation or dislocation of the affected joints.

Muscular weakness and atrophy are often prominent findings in rheumatoid arthritis and in some they are the characteristic features of the invalidism. Atrophy in the muscles of the hands is often advanced However, atrophy occurs in all the muscles of the extremities of which the joints are affected It seems that the atrophy of the muscles is an integral part of the disease and is not solely attributable to disuse and muscular malnutrition Atrophy is not limited to the muscles, joints and

by them: (1) lipoma arborescens and (2) ganglion (see Diseases of Tendons, this chapter).

Lipoma Arborescens. In obese women of about middle life it is very common to find below either the medial malleolus or the lateral malleolus a lobulated, flat, tumor-like mass. This is the well-known lipoma arborescens. It is *very common* and may depend on fatty degeneration of a part of the synovial membrane of the joint.

Joint Diseases Associated With Mechanical Abnormalities. Loose Bodies in Joints. Loose bodies in the joints, such as those resulting from osteochondromatosis, osteochondritis dissecans, loose fragments from *intra-articular fracture*, fractured meniscuses or other foreign bodies, often result in sufficient irritation to produce degenerative joint disease.

When cartilage or bone is torn loose in a joint cavity, the fragments become worn slowly so that they can move freely about inside the cavity, sometimes giving rise to recurring attacks of pain, swelling and disability by their mechanical interference with joint movements Loose bodies in a joint produce symptoms only when they oppose the actions of the joint. The common symptom is locking of the joint, which almost always occurs during flexion. The pain is severe, and often time is required to extend the joint fully after locking. The condition is intermittent. Long intervals may supervene between attacks

The diagnosis is made from the history Often the loose bodies may be visualized on roentgenologic examination when they contain bone or calcified areas.

Spondylolisthesis. This lesion consists of a forward displacement of the body of one of the lumbar vertebrae on the one beneath. The most commonly displaced is the fifth vertebra, which slips forward over the sacrum. The etiology is obscure. The condition seems to be associated with increased lordosis of congenital malformation Surgical intervention may be required The diagnosis is made by the roentgenologist.

[illegible] [illegible]

Classification of these forms of arthritis is not possible; *enumeration can be* made. Such enumerations were published in *Differential Diagnosis of Chronic Arthritis*, by Nutrition Research Laboratories, Chicago, in 1942, and in *Primer on the Rheumatic Diseases*, by the American Rheumatism Association, in 1934 and 1942, and in the *Journal of the American Medical Association* in 1949 Reference *has been made to these sources in this text*

Rheumatoid Arthritis. Synonyms of rheumatoid arthritis are atrophic arthritis, proliferative arthritis, chronic rheumatic arthritis, primary progressive polyarthritis, nonspecific infectious polyarthritis

Five types of rheumatoid arthritis have been defined. (1) the adult type, and four variants. (2) the childhood type (Still's Disease), (3) Felty's syndrome, (4) psoriatic arthritis and (5) rheumatoid spondylitis (Marie-Strumpell arthritis) These diseases were formerly described as separate disease entities. Such descriptions seem to have originated from the fact that rheumatoid arthritis varies greatly in its manifestations in different periods of life It still is not clear that rheumatoid spondylitis is rheumatoid arthritis

1. ***Rheumatoid Arthritis of the Adult Type.*** Rheumatoid *arthritis has a* [illegible] than rheuma- [illegible] 's between the [illegible]

The number and the plausibility of certain current theories of etiology of rheu*matoid arthritis prevent* a definite classification of this disease. A further uncertainty about the cause of this disease has been actuated by the fact that symptomatic improvement follows the use of adrenocortical hormones. The *Primer on the*

liver and spleen in the presence of leukopenia. Some of these patients have subcutaneous nodules of rheumatoid arthritis.

4 ***Psoriatic Arthritis*** (*Rheumatoid Arthritis*). About 3 per cent of patients who have psoriasis have rheumatoid arthritis. This may be only an average tendency for these two diseases to coexist. However, there are those who have psoriasis in whom the arthritic changes occur only in the terminal phalanges of fingers, which show overlying psoriatic lesions of skin and nails. Such may be a distinct form of arthritis, but at present the question cannot be definitely answered.

5. ***Rheumatoid Spondylitis*** (*Marie-Strumpell Arthritis*). Synonyms are spondylitis deformans, spondylitis ossificans ligamentosa or rheumatoid arthritis of the spinal column, ankylosing spondylitis, von Bechterew's arthritis, spondylitis ankylopoietica and spondylitis rhizomelica

The view formerly held that rheumatoid spondylitis was a separate disease entity from rheumatoid arthritis was based on the characteristic course of rheumatoid spondylitis, and difference in response to therapeutic trials.

The etiology of the condition is unknown Presumably it is a form of rheumatoid arthritis often originating in the sacro-iliac articulations, accompanied or followed by inflammation of the apophyseal joints or vertebral facets. It is a disease of young adults and commences between the ages of 20 and 25 years It is 10 times more frequent in men than in women

The manifestations of spondylitis have been arbitrarily divided into three phases: (1) the prespondylitic or early stage, which is characterized by shifting pains of a rheumatic nature in the limbs, thorax and peripheral joints, (2) the "sacro-iliitis" phase during which the patient may be able to carry on his daily work because the discomfort is less marked during the day than at night, several hours after retiring and (3) as the disease progresses, the poker back period which is characterized by pain along the entire spinal column, stiffness and eventual rigidity Rigidity of the spine is not painful though the hip and leg joints are more susceptible to fatigue in this condition

Examination reveals a stiff back with decreased or absent expansion of the thorax during inspiration The degree of disability is largely proportional to the deformity of the spinal column. The spinal column may be bent and ankylosed so far forward that it is difficult for the patient to walk because the head and eyes are directed downward toward the anterior thoracic wall. Lateral deformities of the spinal column may be present, a condition which adds to the disability. This type of ankylosis of the spinal column illustrates well the influence of deformities of the axial skeleton on locomotion

Roentgenologic examination during the prespondylitic stage is not necessary for diagnosis The roentgenogram may be recorded as being negative. The diagnosis can be made from the foregoing history and examination During the phase of sacro-iliitis the roentgenologist may observe definite osseous changes which involve the sacro-iliac articulations As the disease progresses, changes detectable on roentgenologic examination gradually become apparent around the apophyseal joints or articulating facets, the joint spaces appearing narrowed or obliterated. Decalcification of the vertebrae and, still later, calcification of the ligaments is reported by the roentgenologist Gradually the entire spinal column roentgenologically may appear to be fitted with a calcified casing partially obliterating the individual bony structures

The condition may be confused most frequently with osteoarthritis

Once the spinal column becomes fixed, the disease has about run its course. The fixation is permanent.

Rheumatic Fever. T[illegible]
and important forms of [illegible]
association with carditis,

bones, for it often affects the skin. The skin over the crippled extremities is smooth, glossy and atrophic The hands and feet may be cold and dry or cold and wet.

Subcutaneous nodules occur in some patients and are often situated over bony prominences, especially in the region of the elbows and over the ulna just distal to the olecranon They vary in size from those just large enough to be palpable to lesions 3 or 4 cm in diameter. They are not painful. They may become ulcerated and infected The rheumatoid nodule may persist for months to years.

The spleen may be found enlarged A generalized lymph-node enlargement of moderate degree is commonly observed. Iritis and uveitis, often intractable, may accompany or precede rheumatoid arthritis

There is often a hypochromic microcytic anemia of the iron deficiency type which responds little if at all to administration of iron. The leukocyte count, the differential count and the platelets are within normal limits The erythrocyte sedimentation rate is almost always rapid, although a few exceptions of active disease with a normal rate may be seen Hench pays close attention to the trend of the sedimentation rate for he believes it indicates the trend of the disease The roentgenologic appearance of joints varies in different stages of rheumatoid arthritis.

DIAGNOSIS. The appearance and distribution of the joint lesions in those less than 40 years of age which have been described are diagnostic The diagnosis is confirmed by the laboratory and roentgenologic findings At times, in those more than 40 years of age, an extensive survey has to be made in order to differentiate rheumatoid arthritis from degenerative joint disease such as osteoarthritis

DIFFERENTIAL DIAGNOSIS. Rheumatoid arthritis is to be differentiated from degenerative joint disease or osteoarthritis Rheumatoid arthritis is a systemic disease and the patients are sick Osteoarthritis, as a manifestation of aging, affects hyaline cartilage, and the patients are otherwise well Muscular weakness and atrophy and cutaneous changes are commonly associated with rheumatoid arthritis, rarely with osteoarthritis or degenerative joint disease Weight-bearing joints are more often involved in degenerative joint disease, whereas in rheumatoid arthritis the involvement is usually symmetric and generalized. The proximal interphalangeal joints are involved in rheumatoid arthritis, the terminal most often in degenerative joint disease (Heberden's nodes), although occasionally the proximal joints are involved also. In degenerative joint disease subcutaneous nodules are not present, and the erythrocyte sedimentation rate is elevated only slightly if at all Elevation of this value is the rule in rheumatoid arthritis (*Primer on the Rheumatic Diseases*, and in *J.A M.A*, 1949)

There is a chronic type of rheumatic polyarthritis very similar to that of rheumatoid arthritis and differentiable only by a period of observation In chronic gout tophi, an increased serum uric acid concentration and roentgenographic changes serve to differentiate the two Psychogenic joint disease may be differentiated, in some instances only after a period of time.

PROGNOSIS. Some patients who have rheumatoid arthritis recover completely. Often, the disease spontaneously becomes arrested or quiescent at some stage in its course, and the patient is able to carry on activities with limited disabilities. Finally, there are those whose disease advances rapidly to complete invalidism of a most miserable sort It is impossible to forecast the turn of events in an individual patient

2 **Juvenile Rheumatoid Arthritis** (*Still's Disease*) The term Still's disease is employed now to designate the disease of rheumatoid arthritis as it occurs in children. Children who have Still's disease have been observed to carry the disease into adulthood.

In Still's disease the joints have the same appearance as in adult rheumatoid arthritis, and there may be subcutaneous nodules

3. **Felty's Syndrome** (*Rheumatoid Arthritis*). The term Felty's syndrome is employed to designate rheumatoid arthritis which is accompanied by an enlarged

faces. Subsequently the irregularities increase and the cartilage is more deeply affected. The cartilaginous surface may show wide erosions and splits, which penetrate to the epiphyseal bone. Macroscopic fragments of cartilage may be separated and dislodged into the articular space. There is active growth at the periphery of the joint membranes where cartilage and synovial intima form a zone of transitional tissue. Marginal proliferations arise at the juncture of periosteum and fibrous synovial capsule, and from subchondral bone, which produce the bony spurs, lipping or osteophytes. These changes represent an advanced phase of osteoarthritis. True ankyloses do not occur, although calcification and osseous bridges are found in some joints and in interspinous ligaments, leading to variable degrees of rigidity of the vertebral column.

SYMPTOMS. The disease commences with mild stiffness and aching pain in or about the affected joint. Constitutional manifestations are lacking.

Despite the steadily progressive anatomic changes which have been demonstrated in most persons more than 60 years of age, the frequency of symptomatic illness from this process is not great even in older patients. Pain from an osteoarthritic joint is often referred to distant parts, for instance, referred pain from vertebral joints may pass around to the abdomen.

EXAMINATION. On examination passive or active motion, especially in the extremes of range, may produce pain Palpation of the joint during motion may elicit crepitus. Tenderness may be present at the articular margins. There may be spasm and tenderness of the associated muscles As the disease progresses, there is gradual, firm or hard, irregular enlargement of the affected joints. In the terminal interphalangeal articulations there may be tenderness and soft swelling. Generally articulations which are subject to greater strain, such as the knee and hip joints and the lower spinal articulations, show the greater disturbance of function. The terminal interphalangeal joints show greater changes in size and function than the proximal interphalangeal joints. The localization of the disease, however, affords no absolute diagnostic criterion There are no laboratory findings indicative of osteoarthritis.

DIAGNOSIS A progressive but often intermittent articular aching, relieved on rest, with minimal physical signs of joint disease in a middle-aged person without evidence of general illness, suggests the diagnosis of osteoarthritis The diagnosis of advanced osteoarthritis or degenerative joint disease is distinctive when it affects the smaller finger joints of the hands with firm or hard, knobby enlargement leading eventually to ugly deformities and limited range of motion

The phenomenon of referred sensations and pain from the thoracic and lumbosacral segments to the trunk and lower extremities in those who have osteoarthritis is common Neuralgias localized to the occipital, frontal, retrobulbar or other regions of the head may have their origin in foci of cervical spondylosis

The course of osteoarthritis is slowly and steadily progressive over years without severe acute attacks of joint redness and swelling unless the joint or joints are traumatized After acute trauma it may be, for a while, difficult to determine whether the patient has osteoarthritis or rheumatoid arthritis except by roentgenologic examination

NONARTICULAR RHEUMATISM

Often the term nonarticular rheumatism is employed to designate a rheumatic disease that does not affect the joints and that is associated with one or another of a large variety of illnesses. Nonarticular rheumatism is poorly defined clinically and pathologically, so that there is lack of agreement about the prevalence of this protean rheumatic ailment and the importance of differentiating it from arthritis.

Among the diseases associated with nonarticular rheumatism should not be included the many febrile illnesses, particularly infectious diseases of specific causation, which in prodromal or early stages are frequently accompanied by rheumatic symptoms which may constitute the patient's chief complaint. As these ailments progress their nature becomes evident so that differentiation from primarily rheu-

a long time those referable to the heart (see Chronic Disease and Allergy, Chapter 18).

Rheumatic fever either in children or in adults is characterized by (1) migratory polyarticular joint involvement, (2) the presence of carditis, subcutaneous nodules, pleuritis, erythema marginatum and chorea, and (3) a quick response to the anti-rheumatic action of salicylates. The joint involvement is acute and is accompanied by a temperature of 101 to 104 F (38.3 to 40 C), leukocytosis and rapid erythrocyte sedimentation.

The diagnosis can be made on the clinical findings.

Palindromic Rheumatism. Palindromic rheumatism is a rare disease characterized (according to Hench) by multiple afebrile attacks of acute arthritis and periarthritis, sometimes also para-arthritis, with pain, swelling, redness and disability generally of only one, but sometimes of more than one, small or large joint of adults of either sex. The attacks appear suddenly, develop rapidly, generally last only a few hours or days, then disappear completely, but recur repeatedly at short or long irregularly spaced intervals. Despite the frequent recurrences and the transitory presence of an acute or subacute inflammatory polymorphonuclear exudate in articular tissues and cavity, there is little or no constitutional reaction or abnormality in laboratory tests; and no significant functional, pathologic, or roentgenographic residues occur even after years of disease and scores of attacks.

The chief points which distinguish palindromic rheumatism from rheumatoid arthritis are the tendency for only one or two joints to be involved in an attack; the frequent isolated short attacks of para-arthritis, the absence of significant constitutional reactions, and the persistently negative roentgenograms. The greatest and most convincing difference is the persistent absence of chronic arthritis even after many attacks extending through years of the disease There appears to be little or no tendency for the disease to become chronic in a given joint.

Osteoarthritis (*Degenerative Joint Disease, Hypertrophic Arthritis*) The following are several varieties of osteoarthritis, each representing different manifestations of the same disease process. (1) Heberden's nodes (affection of terminal phalangeal joints; (2) malum coxae senilis (morbus coxae senilis, affection of hip); (3) osteoarthritic spondylitis (spondylosis, affection of spinal column) Osteoarthritis may be further subdivided according to the extent of the involvement, as follows: (4) generalized—characterized by hypertrophic changes, principally in the terminal phalangeal joints of the fingers, in the knees and vertebrae, although other joints may be affected, the pathologic changes produced in the articular structures by the wear and tear of daily activity, which are apparent in most people after the age of 50 years, are included in this group, (5) localized—one or two joints are affected which have previously been injured by (a) trauma—secondary osteoarthritis following fractures or injuries, (b) infection, (c) structural abnormality (congenital and acquired deformities acting as stresses), (d) poor posture and (e) muscular imbalance.

The causation of osteoarthritis is unknown The primary change is one of degeneration which is correlated with both advancing age and functional stresses such as weight-bearing. Deterioration of cartilage in the weight-bearing areas, for instance of the knee joint, may be demonstrated in some persons as they approach 20 years of age Osteoarthritis occurs with great frequency and in many joints between the ages of 20 and 40 years and is present in most persons past 60 years of age Contributory factors are occupational stresses, obesity, malposture and habit spasm Wear and tear are also increased by functional derangements or mechanical defects within a joint. The clinical manifestations are seen more often in women than in men Heberden's nodes occur more frequently in women, and a sex-linked hereditary predisposition for this classic feature of osteoarthritis seems to be definite.

Early pathologic manifestations are small pits and irregularities of the articular sur-

examination may be diagnostic. Fragments of the tendon are one source of joint mice.

Chondrodystrophia Foetalis. This disease often is erroneously termed osteogenesis imperfecta and achondroplasia. Chondrodystrophia implies a nutritional disorder of the cartilages in fetal life, which seems to be true. Achondroplasia signifies an entire absence of the normal activity of the cartilage in producing osseous tissue, which in fetal rickets is not true

Chondrodystrophia foetalis is a rare disease of the skeleton beginning in fetal life and affecting those bones preformed in cartilage. Heredity is fully established as an etiologic factor. The characteristic features are present at birth; a moderately enlarged head, depression of the root of the nose, trident hands and remarkably short and curved extremities (micromelia).

Nearly all of these dwarfs die between the seventh and ninth months of intra-uterine life Of those living at birth the majority succumb within the first few months The few who survive the first year or two develop without impairment of their general health and apparently have the same life expectancy as do normal persons If the chest is well formed, since the disease is primarily one of deficient bone growth, after the age of maturity a normal life is expected Many have lived to extreme old age. These survivors are termed chondrodystrophic dwarfs Dwarfs of this type often are featured in sideshows of circuses and carnivals

The adult chondrodystrophic dwarf (achondroplast) presents the same general characteristics as are seen in the fetus There is an abnormal development of the skeletal muscles and short bones which gives a strength relatively much greater than that of the normal man The posture is erect except in the lumbar region, where there is marked lordosis due to the forward tilting of the sacrum The face appears small because of the enlarged calvarium. The nose and the nasal region are flattened, and there is a retraction at the root of the nose. The end of the nose is hypertrophied and rounded The extremities, like the nose, are symmetrically and equally involved by a shortening in the proximal or root segment (rhizomelia) The arms are so much shortened that the fingertips barely touch the crest of the ilium. Complete extension of the elbow joint is impossible and motion in the shoulder articulation is limited The hands are diminutive, short, broad and pudgy The fingers are of about equal length, taper, and distal to the second joint they are separated from each other like the spokes of a wheel, hence the name trident hand (*main en trident*). The legs too are short and the femur and tibia are bowed Malposition of the knee joint and relaxation of the joints of the toes are common The sexual organs often are overdeveloped. An enhanced sexual appetite is common to both sexes.

The principal diagnostic features of chondrodystrophia are the fetal origin, macrocephalic and brachycephalic head, depressed root of nose and prognathous jaws, normal trunk, stunted growth of the extremities with resulting decentralization of the midpoint of the body, bone deformities, lordosis, trident hand, general excess of subcutaneous fat with thickened, loose skin, protuberant abdomen, normal mentality and the roentgenologic findings

Ochronosis. Ochronosis is an indefinite disease entity characterized by darkening of the cartilages of the ears, nose, ribs and in later life of the intervertebral disks. It is a rare disease

Three groups of cases are distinguished respectively by the presence of (1) alkaptonuria, (2) staining of cartilages and tissues from the prolonged use of carbolic acid and (3) staining of the cartilages from melanin, which is a derivative of proteins

In the presence of progressive destruction of the cartilage there are the symptoms of a destructive joint disease such as occur in osteoarthritis.

Transmitted light will help to detect the contrast in color, for instance in the

matic diseases is usually not difficult. Varying degrees of nonarticular fibrous tissue abnormalities are usually associated with different forms of arthritis; this secondary fibrositis contributes significantly to the patient's discomfort and disability. It is important, however, to appreciate that there are many forms of nonarticular rheumatism which occur entirely independently—primary nonarticular rheumatic diseases. This group of ailments includes fibrositis, generalized; fibrositis, localized; lumbago, painful stiff neck; bursitis, periarthritis (para-arthritis), tendinitis (tendon-attachment syndrome), tenosynovitis; fasciitis, panniculitis, herniated subcutaneous fat; herniated muscle, shoulder-hand syndrome; and psychogenic rheumatism, for instance, rheumatic manifestations of psychoneurosis.

PRIMARY NEOPLASMS OF THE JOINTS

Benign Tumors. The benign tumors of the joints comprise cysts, xanthomas, hemangiomas, giant cell tumors and synoviomas These benign tumors are usually not diagnosable by clinical means Roentgenologic examination may or may not be conclusive The diagnosis is made from biopsy of the tissue and histologic examination.

Malignant Tumors. Malignant growths of joints occur with only moderate frequency and may arise from any of the articular tissues Joints may also be involved secondarily by neoplastic processes of the adjacent bone or remote parts of the body These metastatic lesions are especially important when they involve the spinal column and must be kept in mind when back pain is extremely severe.

The diagnosis is established by the history, the physical and roentgenologic examinations and histologic study of biopsy tissue of the tumor. Sarcoidosis, though not a malignant tumor, may produce changes and arthralgias resembling those of malignant tumors of the joints

DISEASES OF CARTILAGE, LIGAMENTS, TENDONS, BURSAE AND FASCIA

CARTILAGE

Injury to Cartilage. At the time of the acute manifestations of joint injury it may be impossible to detect evidence of trauma to cartilage However, the cartilage of a joint may be injured without fracture and perhaps without tear of the joint capsule When a fracture extends into a joint, the joint cartilage is always injured. In such an instance the fluid in the joint will be bloody and will be demonstrable by aspiration.

Semilunar Cartilage. Injury to the semilunar cartilage of the knee may consist of a dislocation or actual rupture or tearing of it The internal semilunar cartilage is most commonly injured by a severe twisting and hyperextension of the knee. Depending on the circumstances and the degree of an injury, it may consist of a detach- [illegible] the knee [illegible] ng of the knee with inability to extend the joint is a [illegible] tally considerable fluid accumulates in the joint Replacement of the cartilage often occurs spontaneously or may sometimes be achieved by cautious flexion and rotation of the tibia. If replacement is successful, it is indicated by the ability to extend the leg completely.

The diagnosis may be established by the forementioned signs when they are acute. However, the condition may not be suspected for a long time. If not, and if there are changes in the density of the cartilage, the findings on roentgenologic

Sacro-Iliac and Lumbosacral Sprain. Back pain and often serious disability attend sacro-iliac and lumbosacral sprains. Local muscle spasm, tenderness and pain on movement are the important manifestations. These disabilities may develop [illegible]

workmen who have sustained injuries of the lower part of the trunk, represent an especially difficult diagnosis. Sacro-iliac and lumbosacral sprains are to be distinguished from coccygodynia and various types of synovitis, neuritis, sciatica and bursitis in the region of the back and hip.

TENDONS

Many tendons move in sheaths which are structurally similar to joints and bursae. They are frequently involved with acute and chronic inflammations when the nearby joint is thus affected. In general, however, tendons are not frequent sites of primary serious disease. Acute infections, wounds and tumors of tendons occur.

Prenatal influences as a cause of disease of the tendons may be manifested by a stenosis of tendon sheaths, for instance, a trigger finger or a snapping finger is often of congenital origin.

Infections of Tendons (Tenosynovitis). Tenosynovitis is characterized by a spindle-shaped swelling of the tendon sheaths, which often move with the tendons. On movement there is pain. The skin may be reddened over the inflamed sheath. On palpation of such a spindle-shaped swelling, grating may be felt on movements of the tendon.

In tenosynovitis of the palm of the hand or of the wrist, if accompanied by a purulent exudate, there often is a severe inflammation. A stiff, deformed hand is too often the sequela of the infection.

The diagnosis can rarely be made of bursitis or tenosynovitis as a separate entity since these conditions so frequently accompany joint disease. Occasionally, as the result of trauma, tenosynovitis of the tendons about the wrist can be diagnosed.

Stenosing Tenovaginitis. Stenosing tenovaginitis of the extensor and abductor tendons of the thumb (De Quervain's disease) is a rather common condition. The disorder may produce considerable disability due to pain in the thumb, wrist and forearm. It is commonest in middle-aged women who use the wrist and thumb excessively. Chronic trauma is the most frequent exciting cause. The pain, at first dull, localizing in the region of the radial styloid and extending into the thumb and hand and up into the forearm, is often neuralgic in character and may be worse at night than in the daytime. It is aggravated by motions of the thumb and wrist. In some cases the syndrome is bilateral. There is swelling over the tendon sheath and localized tenderness over the tip of the radial styloid process. A circumscribed thickening of the tendon sheath may be found on palpation, and frequently a cartilaginous thickening is felt over the styloid process situated under the skin, not adherent to underlying bone, and moving with flexion and extension of the thumb. The pathognomonic sign may be noted on grasping and quickly abducting the thumb ulnarward. The pain over the styloid tip is excruciating. Roentgenologic studies do not reveal abnormalities.

Tuberculous Tenosynovitis. Adams and his co-workers analyzed the diagnostic and therapeutic features in a number of instances of tuberculous tenosynovitis. The youngest patient, complaining of symptoms that had lasted a year and a half, was 15 years of age, the oldest patient was 75 years of age and had had symptoms for 3 years when first seen. The influence of use on incidence was shown by the high involvement of the right hand.

Tuberculosis elsewhere in the body and trauma seem to be predisposing causes

cartilage of the ears. The discoloration of the cartilage and the presence of homogentisic acid in the urine are diagnostically helpful. A biopsy of the skin may be of value.

Osteochondromatosis. Osteochondromatosis is a condition in which cartilaginous and osteocartilaginous bodies are formed within and by the synovial membranes of joints and, occasionally, bursae and tendon sheaths.

The formation of these cartilaginous and osteocartilaginous bodies follows the same stages that occur in the embryonic formation of cartilage. As the bodies increase in size, they may be forced to the surface to become pedunculated. When the pedicles break, as they frequently do, the bodies become avascular and the bone in them dies. The cartilage cells near the surface live, nourished by the synovial fluid. The loose bodies are white and round or oval with a smooth or faceted surface. In number they vary from a few to hundreds.

Osteochondromatosis occurs more frequently in males than in females and is usually monarticular The knee joint is involved by far the most frequently, with the elbow second. Other joints, affected relatively rarely, are hip, shoulder, wrist, ankle, temporomandibular, metacarpophalangeal and interphalangeal. Bursae and tendon sheaths are seldom affected

SYMPTOMS. The symptoms are weakness, aching and progressive limitation of motion of the joint. In due time catching or locking of the joint may occur, although it is usually of a transitory nature followed by slight effusion, pain and stiffness. There is rarely spontaneous pain except with an episode of locking. The minority of patients mention feeling movable masses.

EXAMINATION The joint may be normal to examination. Loose or fixed bodies may be felt The joint capsule is thickened somewhat with moderate effusion present. The motion of the joint may be decreased, although usually not markedly.

DIAGNOSIS. In many instances in which large numbers of bodies are present, they are demonstrable by roentgenogram. Rice bodies (corpora oryzoidea), associated with chronic infections such as tuberculosis, are differentiated with ease microscopically and relatively easily on the basis of history and findings. When there are only a few bodies present, the differential diagnosis may become difficult because loose bodies may be produced in osteoarthritis, in osteochondritis dissecans, and occasionally after trauma. When the bodies are not radiopaque, the conditions in the knee joint must be differentiated from a torn meniscus. In the latter condition the symptoms are relatively more severe, particularly early in the course of the condition

LIGAMENTS

Sprain (Rupture of Ligaments). Trauma often ruptures the supporting structures of a joint but does not involve the joint itself Such injuries are designated as sprains Sprains are to be suspected in every severe injury about a joint, especially if there is exquisite tenderness over the ligaments and not over the bone. A severe pain which develops on certain motions only, is suggestive of a sprain if a fracture is not present

Sprain of the Ankle. It has been shown that in many sprains of the ankle there is a tearing off of small fragments of the bone The term sprain fracture is applied to such injuries

Sprains of the ankle are often the consequence of a lateral displacement. The resultant injury is frequently in the subastragalus and sometimes in the adjacent tarsal joints. This condition is suspected when the pain and swelling are located below and in front of the ankle rather than around the ankle. A sprain, however, is most frequently the result of inversion rather than of eversion of the foot. In eversion, because the plantar ligaments are strong the force is transmitted directly to the ankle and leg bones, and thus the ligamentum deltoideum is ruptured. A Pott's fracture often accompanies this sprain.

tendons or muscles which lie over them to glide smoothly against underlying bone or other structures. In superficial locations the bursae protect underlying structures from trauma inflicted over them. Bursae likewise serve to facilitate skeletal movement.

Some bursae occur naturally. Bursae may form, however, in response to special needs when certain movements are repeatedly used. Some bursae, particularly those about the knee, are continuous with the joint cavity, and they are similar to joints in their reaction to injury

Bursae are rarely the sites of acute pyogenic infection except after injury and infection The commonest lesions of bursae follow trauma, which is sometimes direct and acute, but more often is the result of repeated slight injuries, as observed as the cause of prepatellar bursitis.

Of the almost 150 bursae in the body, all those of clinical importance are situated near the major joints

Acute Traumatic Bursitis. An acute traumatic bursitis may follow direct blows, but more often it results from the same type of forceful movement which gives rise to ruptured tendons or ligaments.

There are so many bursae in the body that the symptoms of acute inflammation and injury cannot be described for each of them Indeed such a description is not necessary, for the symptoms are the same except for their situation, depending on the bursa involved

Often acute traumatic bursitis develops rapidly after a relatively slight injury, provided the bursa has been previously injured by repeated insults or irritations The symptoms are local pain and swelling The pain is severe if aggravated by certain motions The swelling is apparent only in the superficial bursae.

There is often point tenderness over the bursa. The disability frequently is severe on account of the pain, limitation of motion and muscle spasm Occasionally infection develops in the bursa and progresses to suppuration

Chronic Bursitis. Chronic bursitis may follow acute bursitis, but frequently it develops insidiously.

The pathologic changes in chronic bursitis are similar to those in the joint since chronic bursitis is often associated with chronic disease of the adjacent joint Fluid is present and villous overgrowth of the bursal lining occurs In addition, however, calcification of the wall of the bursa is frequent and often is revealed in a roentgenogram.

The symptoms are pain, often severe, brought about or aggravated by certain movements which tend to compress or irritate the bursa.

Tenderness is often localized to the region of the bursa. Swelling may develop because of effusion, which is always present and may be demonstrated by aspiration

The diagnosis can be made on the basis of the situation and localization of symptoms if the examiner is aware that a bursa is situated in that particular location When calcification is present, the diagnosis is made on the basis of roentgenologic examination Excision of the bursa is often indicated and is frequently curative, especially when the bursa is calcified.

FASCIA

Dupuytren's Contracture. This is probably an hereditary disorder which does not become manifest until middle age It is a contracture of the palmar fascia, not of the tendons, and the ulnar side of the palm which causes flexion deformity of the

[illegible]

palpated Herniated fat, opportunely situated, may cause a segmental nerve distribution of pain The small herniations of fat may occur along the sides and lower part of the back.

in some instances. Other tendons may be involved, but the tendons of the wrist are by far the most commonly affected.

The patient complains of a gradually developing, painless or slightly tender mass on the volar aspect of the hand There is stiffness with inability to flex or extend the fingers completely, and diminished strength on grasping The temperature may rise to 99 6 or 100 6 F (37 5 or 38 C).

On examination there is a spindle-shaped swelling along the course of the tendon. Finger motion in the later stages of the disease may cause creaking or grating sounds because of degenerated fibrinous deposits within the tendon sheath—so-called rice bodies. Joint stiffness and a fluctuant mass often indicate osseous disease, which may be proved by roentgenologic demonstration of destruction of the carpus. The diagnosis is proved by biopsy and by inoculation of guinea pigs.

Tuberculosis of the tendon sheaths should receive the same systemic treatment accorded to tuberculosis of the lungs or spinal column. Surgical treatment without knowledge of how the lesion is progressing elsewhere in the body involves the likelihood of operating in the presence of advancing or exudative disease.

Traumatic Tenosynovitis. Traumatic tenosynovitis is rarely serious, but it is a common injury of tendons It produces an inflammation of the sheath with outpouring of an excess amount of the lubricating fluid.

On examination there is local tenderness along the course of the sheath, and use of the tendon produces pain On motion of the tendon creaking or crepitation may be audible Later, fibrous tissue may replace the fluid and fibrin, thereby resulting in limitation of motion.

A dislocation of a tendon may occur so that the tendon leaves the groove it normally occupies and finds a new, abnormal site The tendons commonly involved are the long head of the biceps, the peroneal tendons and the posterior tibial tendon. Treatment consists of operative replacement of the tendon and rest for a week or two until movements without pain are possible

Painful Tendons. Tendons may become inflamed, although more often they are painful without evidence of inflammation, accounting for the symptom complex known as tendon attachment pain This may result from trauma or from more than customary use, with or without regional bursitis. This is a common difficulty, known as tennis elbow, at the attachment of the conjoined tendon onto the humeral epicondyle.

Ganglion. Ganglion is a term applied to a smooth rounded mass (0.5 to 1 5 cm. in diameter) which commonly presents itself in the distal portion of the wrist on the dorsal surface and may be made more prominent by flexion of the wrist. It also occurs on the ventral surface of the wrist and in some other joints, particularly the knee It is found in women much more frequently than in men

Ledderhose has shown that the ganglion originates from the fibrous tissue of the joint capsule as a neoplasm The cystic nature of the tumor is explained by the presence of secreting mesothelial cells or by mucoid degeneration of the fibrous tissue. The lumen of the cyst is commonly a closed cavity, but occasionally it communicates with the wrist joint or a tendon sheath

The first symptom is the presence of the tumor. Later there is pain or discomfort which may result in definite disability

The round cystic tumor attached to a tendon is usually sufficient for diagnosis. Breaking the cyst with a well-directed blow such as that obtained from the flat surface of a book is sometimes followed by cure but is not recommended The tumor, if producing disabling symptoms, should be surgically excised.

BURSAE

Bursae are related to joints in that they are potential cavities lined by modified fibrous tissue or mesothelium which secretes a mucoid lubricant and thus enables

improvement of symptoms by the use of heat and massage and by the administration of acetylsalicylic acid are the characteristic symptoms of primary fibrositis. These same characteristics are observed in rheumatoid arthritis

The differential diagnosis of periarticular fibrositis and rheumatoid arthritis is based on evidence of intra-articular disease (such as an increase in synovial fluid), synovial swelling, and roentgenographic signs of the disease. Indirect evidence comprises capsular swelling, redness and tenderness, loss of weight, anemia, rapid sedimentation rate of erythrocytes, muscular atrophy and limitation of the range of movement of the joints. During the beginnings of either disease the diagnosis may have to wait until the manifestations are definite.

A patient who has *psychosomatic rheumatism* has pain or stiffness which is more adequately described as a sensation of fatigue and weakness than as actual discomfort. The patient feels that movement of an arm or leg is impossible, but when he does move it, the act of movement does not increase the discomfort Pains in psychosomatic rheumatism rapidly migrate beyond all bounds of a nerve and muscle group distribution They go up an arm, down through the body and out through a leg and foot.

Fatigue, especially nervous fatigue, accentuates the symptoms of psychosomatic rheumatism or primary fibrositis. Mental stimulation resulting from a party will relieve the pain of psychosomatic rheumatism for hours This is not so in the case of primary fibrositis

Acute or subacute primary fibrositis usually lasts only a few days or a week or two and disappears without any apparent residua Chronic primary fibrositis may persist for years but the patients usually are able to continue their work and customary activities.

DISEASES OF THE BONES

It is not always possible to determine whether a disease of bone originated in the affected bone itself, in the structures of an adjacent joint or as the result of some systemic disease For this reason uncertainties in regard to classification of some bone diseases are inevitable.

The age of the patient may be helpful in the identification of the nature of a bone disease; for instance, acute osteomyelitis is common in children but is rare in adults Separation of the epiphyses occurs only in children As age advances, however, the bones grow more fragile, and an old person may fracture the neck of the femur by such slight trauma as catching a toe in the bedclothes

When the shafts of the long bones are soft and become curved, deformities arise (for example, bowlegs). It may be possible to demonstrate an abnormal softness by producing a passive curvature If the bones are spontaneously bent near the joints, as in genu valgum, the deformity may be less noticeable Deformities of the feet (talipes), of the hands and of the spinal column make up a large part of common deformities of bones

The common deformities in the spinal column are curvatures with a convexity backward (kyphosis), forward (lordosis) or to the side (scoliosis). Distinction is made between the deformities of curvatures and the angular deformity (gibbus), so characteristic of caries of the vertebrae and those resulting from some fractures.

In the long bones of the extremities curvature arising from softening of the whole bone is most often due to rickets or osteomalacia, whereas angular deformities are due to local affections of the bone such as those resulting from pyogenic organisms, tuberculosis, brucellosis, Paget's disease, hemangioma, metastatic malignant lesions and syringomyelia.

Asymmetric shortenings of the extremities may be due to nervous lesions or to [illegible] epiphyseal cartilage during growth Shortening of one leg causes tilt-

Fibrositis. Synonyms for fibrositis are myofibrositis, muscular rheumatism and myositis. The disease occurs in primary and secondary forms. The *primary* form of fibrositis is a nonsuppurative, acute, subacute, or chronic inflammation of fibrous tissue without demonstrable, systemic disease. It may involve fibrous tissue in any part of the body. *Secondary fibrositis* is a nonsuppurative inflammation of fibrous tissue that is a manifestation of a systemic disease or is due to a local injury or strain. It may be a prominent manifestation of such systemic diseases as rheumatoid arthritis, osteoarthritis, rheumatic fever, gout or lupus erythematosus. It also may be due to gonococcic, streptococcic, staphylococcic or meningococcic septicemia or to the toxemia caused by such diseases as typhoid fever, dengue or influenza. Traumatic fibrositis is secondary to an acute injury. It also may develop insidiously as a result of strains of fascia, tendons or joints owing to poor posture, as observed in scoliosis and flat feet.

The cause of fibrositis is unknown. No changes have been demonstrated in synovial fluid or in the intra-articular membranes.

SYMPTOMS. The symptoms in primary fibrositis may be acute or subacute. Often there are muscle pains and mild discomfort. However, there may be recurrent attacks of varying severity which last only a few days or weeks. The attack disappears without residua but will recur. After several attacks, chronic fibrositis may ensue. Seldom does primary fibrositis start insidiously. A characteristic of primary fibrositis is its variability and its tendency to shift to other regions. Only occasionally in an acute attack will there be a slight rise of temperature and minimal local swelling. A prominent manifestation is subjective stiffness of the affected areas with the very first movements as soon as the patient awakens in the morning. After moderate exercise the affected regions feel better. Later in the day, however, the aching and subjective stiffness may return and get worse. The affected regions seem to "jell" with inactivity and improve with moderate exercise. The subjective stiffness and aching are often affected by changes in the weather, exposure to a draft or air conditioning. Acetylsalicylic acid and local application of heat afford relief.

The *localized forms* of fibrositis give symptoms peculiar to the topographic and anatomic situations, as follows:

Periarticular fibrositis most frequently is the result of trauma, rheumatic fever, rheumatoid arthritis, gout, gonorrhea or periarthritis. It causes local regions of tenderness and may produce swelling of the side of the capsule of the joint. If the disease is acute, the periarticular tissues may be acutely inflamed and painful. Any movement of the joint may be so painful that it cannot be tolerated. If the disease is chronic, inactivity causes subjective stiffness but this is relieved by moderate exercise.

Tendinous and fascial fibrositis most frequently is associated with Dupuytren-like contractions, injury of the supraspinatus tendons, gout, gonorrhea or rheumatoid arthritis that affects the tendons, especially the tendo achillis. It causes localized pain and tenderness, especially when the affected tendon or fascia is stretched.

Perineural fibrositis is an accidental involvement of the fibrous tissue in this situation. It always is associated with periarticular or intramuscular fibrositis near the affected nerve and elsewhere. It produces pain along all or part of the affected nerve. It is particularly likely to involve the intercostal, sciatic and brachial nerves.

EXAMINATION. There is no demonstrable synovitis or intra-articular disease, no juxta-articular atrophy of muscles, no loss of weight, and no roentgenographic evidence of arthritis.

On examination of the affected areas there will be found tender nodules, cords or bands in the muscles, fascia, or articular capsule in about one half of these pa- [illegible] s level and the sedi-

[illegible] elieved by moderate [illegible] ges of weather, and activity, aggravation of symptoms by exposure and by changes of weather, and

movements that do not occur normally in the joint In unimpacted fracture of the neck of the femur the lower extremity can be shortened by compression in the long axis or lengthened by traction in this axis. Such abnormal mobility is associated with local pain; absence of such pain points either to an old lesion or, if recent, to analgesia due to tabes or to syringomyelia.

Palpation may be extended and refined by the use of a probe in case a fistula or a sinus exists. On probing, if the bone is bare, the raw bone can be felt as grating; if it is insensitive, the bone is necrotic.

Ossification of Bones. A knowledge of the normal times for the completion of ossification is important in the diagnosis of many bone disorders of younger patients.

Apart from the clavicle and the majority of the skull bones, which are ossified in membrane, the others undergo intracartilaginous ossification. Interference with the ordinarily regular sequence of ossification of the bone may result from hereditary, congenital or acquired causes The resulting diseases are all rare, and certain ones affect membrane bones, while others affect only those bones preformed in cartilage.

Osteogenesis Imperfecta. *Osteogenesis imperfecta, also designated fragilitas* ossium, brittle bones, osteopsathyrosis and Lobstein's disease, is a rare disease of bones manifested by the presence of multiple fractures after slight trauma. Many instances are associated with blue scleras

Bickel has classified all forms of osteogenesis imperfecta somewhat as follows: (A) *Hereditary Type.* (1) Blue sclera and characteristic roentgenologic changes; (2) white sclera and characteristic roentgenologic changes; (3) blue sclera and atypical roentgenologic changes (B) *Nonhereditary Congenital Type.* (1) Blue sclera and typical roentgenologic changes; (2) white sclera and typical roentgenologic changes

It is impossible to distinguish clinically between the hereditary and the nonhereditary congenital types of osteogenesis imperfecta There is a great variation in the severity of the process, from a disease in the newborn which is so severe as to be incompatible with life, to a suspected condition, which proves to be unrelated, in a patient who is osteogenically healthy

These patients are poorly nourished, short in stature, and deformed. The head tends to be triangular in shape with an increase in its transverse diameter The skulls of infants may feel like parchment, the sutures are open Dentition is poor and the teeth often are soft and carious with a translucent appearance

The axial skeleton is most severely and most markedly affected Scoliosis and kyphosis are frequent and severe. Deformity of the thoracic cage varies and the ribs and sternum often are twisted and molded to conform to the deviations of the spinal column

The deformity of the extremities is dependent on the number of fractures and on the success of alinement of the fragments of bones. In some cases the magnitude of the problem of multiple fractures defeats all attempts at treatment.

Excessive mobility of joints attributable to unusual laxness of the capsule and ligaments may be present. These individuals are prone to have frequent sprained joints and tears of joint ligaments.

Multiple fractures caused by trauma as slight as rolling over in bed are a constant feature. The amount of pain suffered at the time is less than normal In Bickel's series there was an average of 9.2 fractures per case of the hereditary type and of 13 1 fractures per case of the nonhereditary congenital type.

In cases of the *nonhereditary* congenital type the fractures occur earlier, are more frequent and are caused by less trauma than in cases of the hereditary type of osteogenesis imperfecta The fractures are subperiosteal, with little displacement of the ends of the bones but with angulation at the site of the fracture. Many incomplete fractures or regions of absorption (Looser's zones) are revealed roentgeno-

ing of the pelvis, scoliosis and limping. A shortening of the radius or a lengthening of the ulna will cause radial flexion of the hand.

When the bones are softened, as in a severe degree of osteoporosis, or when there has been solution of continuity from fracture, the function of a bone as a supporting organ can no longer be fulfilled On attempting to use the bone as support, so much pain is caused that the attempt is given up. When pain is not felt by a child, the child likely is congenitally insensitive to pain. When pain is not felt by an adult, syringomyelia or tabes dorsalis is suspected.

Local enlargements connected with the skeleton are immobile, a point which helps to distinguish them from masses near the bone, though an external mass may become adherent to an underlying bone and thus be rendered immobile, for instance, a carcinoma of the breast may become adherent to a rib.

The form and the consistency of masses attached to bones, or originating in them, can often be felt on palpation. In unimpacted fracture, crepitation may be palpable When tumors or cysts originate within the bone and lead to atrophy of the bony substance over them, this substance may be reduced in thickness to a thin, paper-like layer that crackles on pressure

In subperiosteal hemorrhage, such as that seen after trauma and in infantile scurvy or, sometimes, in cephalhematoma, new bone may form at the periphery. On palpation a raised circular deformity of bone will be perceptible, which as the palpating hand passes toward the center of the mass, suddenly ceases, giving the impression of a defect in the bone.

On palpation over tumors of bone, especially angiomas, pulsation can often be felt. On palpation of the skull, if a pulsation is observed, it may be due either to a bony tumor or to pulsation of the brain felt through a defect in the bone

In fractures of bones palpation by trained fingers will yield clues to the exact nature of the deformity and displacement In diseases of the upper cervical portion of the spinal column palpation through the pharynx gives access to the vertebral bodies. In diseases of the pelvic bones palpation through the rectum or through the vagina may be helpful in diagnosis

When crepitus is perceived near a joint, the examiner determines whether it is in the joint itself, or due to a fracture of bone or to separation of the epiphysis near the joints In crepitation due to a fractured rib the crepitation may be audible during the respiratory movements Fractures are not always accompanied by crepitation, since the ends of the bones may not be in apposition, owing to marked separation or to erosion of the ends of the bones from tumor, or, again, crepitus will be absent if the fracture is impacted.

In testing the bones for tenderness, gradually increasing pressure and tapping with the fingers may be used. By such tests over long bones and on the spinous processes of the vertebrae, disease of bones and of the spinal column is often localized

Tenderness of the bones may be diffuse, as in leukemia, in the state of exhaustion that follows influenza and rubella, and especially in osteomyelitis, or it may be strictly localized, as in fractures or in bone abscesses. Bone tenderness is commonly present in the neurotic patient.

An important method of eliciting bone tenderness is by compression in the long axis, thus: Press upward from the elbow toward the shoulder in testing the humerus; from the heel toward the pelvis in testing the lower extremity; or from the head or shoulders toward the pelvis in testing the spinal column. In case of suspected impacted fractures, manipulation is carefully performed lest an impaction may be undone which might be desirable to keep

Mobility, where normally there is none, is a sign of solution of continuity, and points either to unimpacted fracture or to pseudarthrosis. To discover such abnormal mobility in the neighborhood of joints, the examiner should try to produce

INFECTIONS OF BONES

(*Inflammatory Osteopathies*)

The infections of the bones comprise osteitis, osteomyelitis and periostitis.

Osteitis. Acute osteitis occurs in conjunction with various bone infections. In the acute form osteitis is rarely a separate entity.

Chronic osteitis is commonly diagnosed by the roentgenologist The clinician can rarely find supporting diagnostic evidence that chronic osteitis is a separate entity. The term also is used to denote diverse bone conditions of noninfectious origin

As a result of infections there often occur (1) atrophy of disuse, (2) subsequent deformities as the result of healing, (3) epiphyseal defects, separations and instability (slipping) and (4) exostosis. During the process of a low-grade infection a fracture may occur, as during syphilitic infections of long bones.

Osteomyelitis. Osteomyelitis may be classified according to its manifestations, as (1) acute (primary), (2) secondary and (3) chronic.

Common sites are the shaft of the femur, the clavicle, scapula, a rib, and the tibia. Any bone may be involved, however, including the bones of the skull, the spinal column, the sternum, and the small bones of the extremities. If the infection of the bone is a virulent one, acute abscesses usually form in and around the affected bone Often a considerable mass of bone dies (necrosis of bone), and the sequestrum will keep up chronic suppuration, with sinus formation, unless an operation is performed.

Acute Osteomyelitis. Acute osteomyelitis is common in childhood, but is rare in adult life It is a hematogenous infection of bone often due to the staphylococcus. The infection may arise from some pre-existing lesion such as a furuncle, septicemia or otitis media However, more commonly it arises through some occult or unknown portal of entry. There is frequently a history of injury at the site of the infection, but its etiologic importance may not be established

Pus under the periosteum strips the membrane from the bone, thus forming a subperiosteal abscess which ruptures into the overlying soft tissue and forms a subcutaneous abscess The amount of bone infected by the disease is not immediately apparent In severe osteomyelitis, when the infection involves the whole medullary cavity, the entire shaft may become necrotic In other instances the infection may break through the cortex so soon that very little bone is invalidated Although the infection rarely penetrates the epiphyseal line, it may precipitate a pyogenic arthritis by entering the joint from without after pus has appeared under the periosteum and extended from there into the joint

There are two reparative processes First occur the separation and partial phagocytosis of necrotic bone, which becomes demarcated from the viable cortex and is called a sequestrum Second, osteogenesis occurs from the lifted-up periosteum, although the new bone, involucrum, cannot be revealed roentgenologically for two or three weeks This new bone, which develops in the presence of the sequestrum, eventually generally becomes dense, hard, and rich in calcium, and replaces the necrotic bone On rare occasions the infection does not extend or penetrate, but forms a localized lesion in bone and is called *Brodie's abscess*, which ordinarily develops insidiously and is really a manifestation of chronic osteomyelitis. From the primary bone lesion metastatic foci may develop, and it is not uncommon for several bones to become infected one after the other. This succession may continue for years so that eventually most of the long bones become invaded by the osteomyelitic process Abnormal lengthening of the affected bone occurs in many children after many months and is apparently due to the increased blood supply, the hyperemia at the epiphyseal line augmenting local bone growth Owing to the preferences of the osteomyelitic process for the tibia, femur, humerus, radius, ulna, fibula and metatarsal bones, the irregularities in length do not cause grave locomotor difficulties. Locomotor disturbances are consequences of the active disease.

SYMPTOMS. The general symptoms are those of general septicemia with fever, chill, rapid pulse and prostration. The extreme pain seems to enhance the prostra-

graphically. The frequency of fractures ceases as puberty is approached and fractures may stop after puberty.

From the foregoing discussion it is clear that only in the rare case without a history of multiple fractures from birth on, is osteogenesis imperfecta likely to be confused with osteitis fibrosa generalisata. The bone disturbance may be first recognized at the age of about 15 or 16 years when roentgenograms reveal a generalized lack of bone density. The very thin, but not decalcified bone rules out the bone disease of hyperparathyroidism The lack of bone density may or may not be accompanied by blue scleras. The concentrations of serum calcium and serum phosphorus are within normal limits. The concentration of serum phosphatase may be slightly elevated. There probably will be a family history of fractures, blue scleras, or otosclerosis. Blue scleras and otosclerosis are not constant features of this disease.

Osteochondrosis of the Capitular Epiphysis (Legg-Perthes-Calvé Disease, Osgood-Schlatter Disease; Köhler's Disease). Osteochondrosis of the capitular epiphysis (Legg-Perthes-Calvé disease, coxa plana) is a disease of the upper part of the femur affecting children between 5 and 10 years of age This disease has been thought to have an infectious element in its etiology and thus the designation osteochondritis deformans juvenilis has been used.

Symptoms comprise slight pain and limp that are soon followed by shortening of the leg This disease may symptomatically resemble coxa vara.

Diagnosis is established by roentgenographic examination The roentgenograms reveal progressive flattening of the head of the femur which is characteristic of the disease. A similar lesion has been described in the tibial tubercle (Osgood-Schlatter disease) and in the tarsal scaphoid (Kohler's disease). Treatment consists of immobilization when pain is present.

Lipochondrodystrophy (Gargoylism or Hurler's Syndrome). This is a rare condition ending in death in childhood. Mental deficiency is associated with malformations of the bones There is dwarfish stature with short neck, curved spinal column, short thick limbs, protuberant abdomen and grotesque face. The nature of the facial peculiarities, somewhat resembling those of cretinism, is not clear Optic atrophy may occur. In many cases enlargement of the liver and the spleen gives rise to suspicion of congenital syphilis. The corneas may exhibit opacities in the deeper layer.

Periodic Arthralgia of Hereditary Origin. Periodic arthralgia is characterized by regular recurrences of pain and often swelling of joints of the extremities, but usually of one or both knees. It is a rare disease. The disease has been known to affect five generations of the same family (Reimann).

The disorder has the characteristics of the Schonlein-Henoch syndrome. Both probably are manifestations of the same underlying cause and represent variant forms of a group of periodic diseases The disorder may begin at any time of life, and the intervals may shorten or lengthen It may last a lifetime or may disappear either spontaneously or in rare instances after certain forms of therapy. Rarely do permanent injury to the joints and other effects on the general health occur The episodes usually recur at regular intervals of 7 to 21 days, last several days, usually without fever or other symptoms or signs, and disappear until the next predictable bout. In some patients recurrences come at irregularly short or long intervals. In some instances there is only stiffness, and in others there is an effusion into the joint or joints.

Biopsy reveals edema of the synovial membrane with or without monocytic cell infiltration of the tissue. Effusion of serous fluid, when present, may contain more than 1,000 cells per cubic millimeter; either polymorphonuclear cells or lymphocytes predominate.

Osteomyelitis of the skull is secondary to compound fracture or a sinusitis. Osteomyelitis is always suspected when an abscess or infected wound located near bone fails to heal and forms a chronic draining sinus.

Roentgenologic examination is required in order to make a diagnosis in secondary osteomyelitis. However, the diagnosis is usually evident from the history, the findings, and the situation and appearance of the lesion.

Chronic Osteomyelitis. Chronic osteomyelitis follows an acute primary or secondary osteomyelitis which has resulted in necrosis of bone The severity of chronic osteomyelitis often depends on the extent of bone killed by the virulence of the infection. An extremity which is the site of chronic osteomyelitis shows considerable muscular and bone atrophy and exhibits one or more draining sinuses leading to the bone. The patient is often shrunken from the toxemia, pain and fever. This disease often is caused by *Salmonella typhosa* after an attack of typhoid fever.

Roentgenologic examination will reveal the extent of the lesion and often will clearly demonstrate the site and size of sequestra

Tuberculosis. The distinction between tuberculosis of the bone and of the joint cannot always be made, since the tubercle bacillus often attacks both structures simultaneously, or seemingly so

Tuberculosis of the Cranial Bones. The infection usually gains access to the middle ear through the eustachian tube and is secondary to infection of the throat, cervical lymph nodes or lungs It may spread from more remote foci, however, by way of the blood stream.

In most cases the process is a sluggish one but in others it progresses rapidly, invading the mastoid bone and the labyrinth. External pachymeningitis, with penetration of the dura resulting in meningitis or formation of tuberculoma, is common The sigmoid sinus may be thrombosed In a few cases tuberculous osteomyelitis of the base of the skull in the anterior fossa has been observed This is apparently due to extension of tuberculous processes in the sinuses and nasal bones

Tuberculous otitis is usually secondary to lesions in the upper respiratory passages The onset is gradual in most cases and is not accompanied by pain. There is a thin, watery discharge at first, but this may later become purulent if secondary infection develops There may be multiple perforations of the drum and later the whole drum may be destroyed. In some cases hearing may be only slightly reduced, in many it is completely abolished A characteristic feature is the presence of paralysis of the seventh nerve, which has been estimated to occur in 40 per cent of all cases. Ford observed cases also in which osteitis of the walls of the orbit resulted in palsies of the third nerve

The infection may extend through the dura, causing tuberculous meningitis or solitary tubercle The latter is most likely to be found in the cerebellar hemisphere or the temporal lobe In instances complicated by pyogenic infections, abscess of the brain or purulent meningitis may result

The diagnosis depends on the evidences of tuberculosis elsewhere in the body, the slow course, absence of pain, the multiple perforations of the ear drum, the frequent presence of facial paralysis and, above all, on the demonstration of tubercle bacilli in the secretions and granulations.

Tuberculous Spondylitis. Tuberculosis of the vertebrae (Pott's disease) is the most serious inflammatory disease of the spinal column, especially in children.

The process is believed to begin in the body of the vertebra and extend to the periosteum, the intervertebral disks and ligaments From 1 to 5 adjacent vertebrae may be affected, and in some there are [illegible] weight-bearing, the bodies of the verte[illegible] kyphos The spinal cord or the spinal ne[illegible] vertebral body extending into the epidural space and compressing them. Generalized or localized tuberculous meningitis may be present Compression of the cord may occur as a result of dislocation and deformity of vertebrae or of the dorsal displacement of a sequestrum

tion. During the first day or two of the disease, before the infection has broken through the cortex of the bone, the pain is severe and it is situated over the end of the bone near the joint. In adults the general reaction is likely to be less marked than in children; subacute and chronic forms are more frequently encountered in which the infection develops slowly.

Streptococcal osteomyelitis differs considerably in its manifestations from osteomyelitis produced by the staphylococcus. The former infection much more commonly occurs as a metastatic invasion of the bone from a primary source such as otitis media or mastoiditis or from a furuncle or carbuncle. The manifestations of the streptococcal osteomyelitis are likely to develop more insidiously than those of the staphylococcal infection. The pain is not so severe; swelling and subcutaneous suppuration develop more slowly and less commonly. There is less destruction of bone, and sequestration is therefore less marked. Many such lesions will subside under proper conservative care without gross suppuration. They are particularly prone to occur in infants.

EXAMINATION. Muscle spasm is often present. The joint can be moved somewhat without increasing the pain. Acute tenderness over the involved bone on deep palpation is one of the earliest signs. In eliciting this tenderness the bone is carefully palpated, starting at some distance from the lesion, which is approached gently and gradually The overlying tissues may be swollen and edematous, but the skin itself is not red or tender during the early stage of the disease. If the infection has been present for several days, there may be evidence of a local abscess, that is, swelling, redness, local heat and fluctuation

DIAGNOSIS. The diagnosis is based on the foregoing findings. The local signs and symptoms are meticulously observed Examinations are repeated at short intervals in order to keep informed in regard to the rapidly developing events. The results of roentgenologic examination are disappointing because the earliest roentgenologic evidence of acute osteomyelitis is absorption of bone, which ordinarily is not demonstrable for a week or more after the onset The diseases which may be diagnostically confusing are acute rheumatic fever, acute pyogenic arthritis and acute cellulitis Involucrum formation requires at least 2 weeks. It is discovered on roentgenologic examination when calcium has become deposited under the elevated periosteum Sequestration may not be demonstrable for an even longer period.

When acute osteomyelitis is suspected, a blood culture, which will often reveal the bacterial cause, should be made It is important to remember that in osteomyelitis during adolescence the urine may contain the etiologic agent.

In the differential diagnosis acute osteomyelitis is distinguished from (1) acute arthritis, especially from acute coxitis, (2) subcutaneous abscess and intramuscular abscess, (3) acute rheumatic fever, (4) ordinary septicemia and pyemia and (5) malarial fever

In general, operation is urgent in staphylococcal infections, not urgent and frequently unnecessary in streptococcal infections.

Secondary Osteomyelitis. This is a bone infection occurring as the result of infection in tissues adjacent to the bone, for instance such as that due to compound fractures.

Secondary osteomyelitis of the jaw often develops by extension from cellulitis about a tooth If the tooth is pulled at the improper time, for instance while the infection is too acute, osteomyelitis is particularly prone to develop and may lead to septicemia

The terminal phalanx may become the site of osteomyelitis during the course of a felon. The other phalanges may be infected secondarily from acute suppurative tenosynovitis. Osteomyelitis of the tarsus is sometimes secondary to penetrating infections and may eventually involve the entire foot. The patella and olecranon are sometimes involved by direct extension from an overlying lesion.

Granuloma Inguinale. Granuloma inguinale of bones occurs during the course of the active infection. The skeletal infection is characterized roentgenologically by osteolytic areas in the bones. In none of the cases so far reported are the roentgenologic changes specific for this disease. Diagnosis is best established by biopsy with search for macrophages containing Donovan bodies (*Klebsiella granulomatis*) when the bone changes occur during the course of granuloma inguinale (see Diseases of the External Female Genitalia, Chapter 7).

Syphilis. Syphilis of the bone may be manifested as chronic periostitis. Syphilitic

either in the secondary or in the tertiary stage of the disease.

During the secondary stage of syphilis a patient who has syphilis of the bone may complain of rheumatic or of neuralgic pains, or of circumscribed tenderness on the bones. The superficial bones (skull, anterior surface of tibia, ulna, metacarpi) are most often painful. The pains are milder in the daytime than at night, when they may become almost unbearable. Nodes, due to subperiosteal deposits, often become palpable.

The usual affection of the bones by syphilis is periosteal gumma formation with necrosis of the underlying bone, followed by ulceration and exposure through the skin or by an extensive osteophyte formation Less common is gummatous osteitis or osteomyelitis with necrosis and erosion of bone

Syphilitic inflammation of the bone may produce a new growth of spongy bone on the surface of the cortex Such proliferations of bone may form a convex layer on the bone cortex which as time passes becomes very hard and solid. However, these cortical layers of proliferated bone are not limited to syphilitic infections, for other nonspecific forms of periostitis can produce the same thing. All of these proliferating bone disturbances occur more commonly in the skull and long bones, especially the tibia, than in other bones

Gummatous osteitis and osteomyelitis may arise in the interior of the bone In the cranial bones the periosteum can be separated by such a process, leaving a coarsely corroded surface If the process is extensive, the skull may be penetrated and destroyed, and left with a ragged hole in it. Comparable gummatous nodes may occur in the tibia, extending into the cortex and marrow cavity, which may circumscribe the bone and cause necrosis of it Gummatous lesions may occur within the marrow cavity and involve it locally or may extend to involve the whole of it without outward evidence of their presence In other instances marrow involvement will be accompanied by a spindle-shaped enlargement of the shaft of the bone

In syphilitic dactylitis there is osteoperiostitis with enlargement and rarefaction and internal destruction of the bone The finger swells and may be easily fractured and subsequent fistula formation ensues When a phalanx or a metacarpal bone is affected, the appearance may resemble that of tuberculosis

In roentgenograms the signs of syphilis of the bone are usually characteristic. Sometimes a circular involvement of the bone is recognizable A positive serologic reaction may not be helpful diagnostically, a negative serologic reaction is definite in that the diagnosis of syphilis of the bone should not be made if the reaction is negative

Syphilis of the bones may resemble tuberculosis, sarcoma, sporotrichosis or even chronic staphylococcic osteomyelitis

Yaws. Yaws is caused by *Treponema pertenue*. In the

man

sheaths are involved which give joint symptoms, but the joint surface is not affected, so that primary joint symptoms are not present.

The serologic reactions are positive. The roentgenologic findings are very much

The spinal nerve roots may be involved by infiltration or by compression when there is collapse of the vertebrae and shortening of the spinal column.

SYMPTOMS The *onset is insidious and* is characterized by pains in the distribution of the spinal nerve roots arising in the affected region of the spinal column In children sleep is broken by night cries as the result of relaxation of the muscle spasm of the vertebral muscles

The pain is usually referred around to the anterior surface of the body. Among other symptoms characteristic of the early stages of the disease are abnormalities of [illegible]

weight, fatigue and perhaps afternoon rise of temperature.

EXAMINATION When the cervical vertebrae are involved, the pain is referred to the occiput, neck, arms or shoulders, depending on situation of the lesion The head may be held rigid, flexed, extended, tilted or rotated to one side. There is strong muscle spasm, and rotation of the neck is resisted. If abscess forms, it may drain into the retropharyngeal space or, less commonly, laterally into the muscles of the neck.

Lesions of the thoracic vertebrae cause the body to be inclined forward. The lumbar lordosis is diminished. The patient walks with caution, often on the toes to avoid jars. When the upper thoracic vertebrae are affected, the shoulders are often elevated and squared. If abscess forms, it drains into the posterior mediastinum and causes dyspnea and cyanosis.

Lesions in the lumbar vertebrae cause increased lordosis. Psoas abscesses may cause psoas spasm with flexion of the hip.

Ford has emphasized that paralysis due to compression of the cord by epidural tuberculous tissue may be present without deformity of the spinal column, without muscle spasm and without demonstrable changes in the roentgenograms of the bones.

Involvement of the spinal cord is from pressure manifested only by weakness and stiffness of the legs without paraplegia or loss of control of the bladder. In instances of lesions below the lumbosacral enlargement paralysis if present is associated with atrophy, flaccidity and loss of reflexes

DIAGNOSIS The diagnosis is based on the presence of loss of weight, retarded growth, fever, changes in gait, altered posture and night cries, muscle spasm and limitation of movement, deformity of the spinal column, positive intracutaneous tuberculin reaction, and the roentgenographic changes in the spinal column In an occasional case there is paraplegia However, 8 of every 10 who have this sort of paraplegia recover in less than one year. In some recovery may be expected after several years.

Periostitis. Periostitis is an inflammation of the covering of the bone which occurs in both acute and chronic forms. Acute inflammation of the periosteum, like osteitis, occurs in association with various disease conditions of bone and as such cannot be definitely diagnosed except by means of roentgenologic examination, which reveals the characteristic increased density about the cortex of the bone.

Acute Periostitis. Acute periostitis follows either trauma, as in fracture or contusion, or infection, as in acute periostitis of the jaw secondary to dental infection. An acute periostitis is not uncommon as a complication of severe fevers.

There are local swelling, extreme pain, and heat. When sepsis is present, suppuration may follow. When the periostitis is of purely traumatic origin, the condition is usually transitory.

The diagnosis is usually easy if the etiology is known. Roentgenologic examinations will differentiate acute from chronic periostitis, since in the latter there will be evidence of bone formation.

active person in plaster casts an acute osteoporosis may arise. An acute osteoporosis is more likely to arise if the patient ingests large amounts of milk and if, in order to accelerate healing of the bone, vitamin D is administered. When the foregoing conditions prevail, the excessive amounts of calcium cause a hypercalcemia and hypercalciuria. The hypercalciuria is the cause of the formation of *renal stones* which occasionally occurs in patients who are in extensive casts. Renal stones seem to be of a higher incidence in those who have fractures of the pelvis and the femur. The formation of renal stones is less frequent in patients who have fractures of the upper extremity.

Anuria in a patient who has extensive immobilization of the skeleton occasionally occurs. If anuria does occur, the urine and the blood are examined for an excess of calcium. If there should be an excess of calcium, the removal of the cast may be a lifesaving measure

In such patients the high calcium content of the serum and the urine may give the impression of hyperparathyroidism. Hyperparathyroidism is a rare disease and its differentiation need not delay the removal of the cast.

Osteoporosis and the Senium (*Senile Osteoporosis*). A characteristic of senility is decreased intensity of protein synthesis manifested by atrophy of skin and muscles and by osteoporosis As the years advance beyond middle age, often the cortex of the bones of the whole skeleton shows signs of atrophy. The trabeculae of the cancellous bone become thinner and further apart, the greater part of the bone marrow becomes fatty, and only a few scattered islands of red bone marrow are in evidence In extreme examples of the disease the vertebrae collapse and the cortex of the other bones may become thin. This is the commonest form of osteoporosis. The skull and extremities are practically always free from osteoporotic involvement, except in the severest forms of the disease, and the lamina dura of the teeth remains normal. The vertebrae are the most profoundly affected

Osteoporosis and Vitamin C Deficiency. In children the commonest evidences of the lesions of scurvy are the irregular broadened epiphyseal line, the lateral spurs and occasional dislocation of the entire epiphysis, the decreased calcification behind the epiphyseal line, the thin diaphyseal cortex, and the rarefied shaft Normal calcification of bones and teeth seems to be dependent on adequate vitamin C. Ascorbic acid deficiency leads to decreased bone matrix formation and in turn to *osteoporosis.*

Adult Scurvy. Scurvy is rare in adults The bone lesions in the adult are limited to subperiosteal hemorrhages as described in infantile scurvy. Intracranial bleeding is spoken of, but it is not common in the adult

The history of deprivation of those foods which contain vitamin C is usually definite except when scurvy occurs during the course of chronic starvation. The concentration of vitamin C is decreased in the blood. Roentgenologic examination of the long bones may be diagnostic

Osteoporosis and Rickets. Rickets is a metabolic disease due to deficiency of vitamin D caused by insufficient exposure to sunlight which produces changes in the viscera, muscles and tendons The characteristic changes in the disease referable to the skeleton which take place at the periods when the skeleton is developing most rapidly (that is, during the first two years of life) extend through to the age of puberty

When there is insufficient absorption of calcium from the intestine, proteinic bone matrix is formed in the normal way but no calcium phosphate is available for deposition As the normal growth or wear and tear of the skeleton go on, there is not enough calcium for growth, or the lost calcium is not replaced, and decalcification or osteoporosis appears (see Chapter 22).

Osteoporosis and Osteomalacia. The reactions of the skeleton in rickets and osteomalacia are fundamentally identical. In both diseases the osseous trabeculae are surrounded by broad osteoid seams, and thus the definition of osteomalacia as

the same as those of syphilis. The bone lesions are benefited by specific treatment for syphilis. The diagnosis depends more on the age of the patient, who as a rule is much younger than one who has syphilitic bone disease It is well not to make a diagnosis of yaws of the bone unless the patient comes from an area in which the disease is *endemic*

Hydatid Disease. Hydatid disease of bone occurs in only a few of those who have hydatid infection The common sites affected are the vertebrae, the pelvis, the femur and the humerus. The vertebrae are the bones most frequently affected. The *spongy tissue of the vertebral bodies* is a favorite site when hydatid disease attacks a bone The infection, as with hydatid disease elsewhere, usually starts in childhood While it is confined to the bone, the growth of the hydatid is so slow that symptoms do not become evident before adult life. There are no symptoms until the destruc*tion of the bone leads to fracture or dislocation or until the hydatid cyst has erupted* from the bone and caused *pressure or swelling*.

The diagnosis of vertebral hydatid disease is uncertain The general condition of the patient is usually excellent Symptoms are due to fracture or subluxation of the affected vertebra or to pressure by extraosseous extensions, which may be confused with lipoma or cold abscess. Although vertebral hydatid disease has no pathognomonic roentgenologic signs, certain features, such as absence of periosteal reaction, minimal collapse, slight involvement of intervertebral spaces only, increased density of bone together with areas of destruction and involvement of contiguous ribs when a thoracic vertebra is affected, aid the roentgenologist in the interpretation of the roentgenogram.

METABOLIC DISEASES OF THE BONES

Metabolic diseases of the bones may arise during the course of malnutrition or as the result of deficiencies of vitamins

Albright has reasoned that the diet is of etiologic importance in the production and the maintenance of bone If there should be inadequate amounts of protein *ingested*, the osteoblasts would be deprived of the necessary strength to produce the *organic matrix* which is the first requisite for the formation of bone To the contrary, if there is an *increased availability of calcium and phosphorus* in the system as a result of a diet rich in these substances there would be a decrease in normal degree of resorption of bone However reasonable these assumptions are, there is no evidence that osteoporosis ever results from an inadequate diet in man.

Osteoporosis and Metabolic Disorders of the Bones. *Osteoporosis* is a disease of the bones characterized by increased porosity from widening of the haversian canals and absorption or lack of calcareous material. Osteoporosis occurs in many *and diverse conditions which permit a decreased* formation of proteinic bone matrix Osteoporosis can be caused by any condition in which the synthesis of protein is impaired. In such instances the calcium taken from the intestine cannot be used for normal bone repair because no bone matrix has been formed It therefore is excreted in the urine Thus, in the initial stages of osteoporosis, hypercalciuria is a frequent occurrence, and occasionally renal stones develop. Osteoporosis occurs frequently in prolonged *immobilization of bone*, in *metabolic disturbances* and *deficiency states*, in the *senium*, in *prolonged semistarvation*, in the *menopause* and in *Cushing's syndrome*.

Immobilization of Bones. The daily use of the skeleton requires a certain *amount of maintenance*. The maintenance of the skeleton is a function of the osteoblasts. During immobilization of the skeleton the normal stimuli for osteoblastic activity are not operative, less proteinic matrix is made by the osteoblasts, and thus *less bone* is formed. In time, often in a week or two, the limb in a plaster cast reveals atrophy of the soft parts and particularly atrophy of the bone.

In instances of immobilization of a large part of the skeleton of a previously

Polyostotic Fibrous Dysplasia. Polyostotic fibrous dysplasia in females is characterized by abnormalities of skin and bone and of endocrine function. The cutaneous lesions are brown, nonelevated, pigmented areas which tend to be on the same side as the osseous lesions. The osseous lesions on histologic examination reveal osteitis fibrosa.

SYMPTOMS. The first manifestation of the disease is a segmental distribution, roughly similar to that of the osseous lesions, of pigmented areas of skin which consist of small or large irregular café au lait spots These lesions are often first observed soon after birth and are similar in every respect to the forme fruste of Recklinghausen's disease.

The skeletal manifestations are varied. They may be without symptoms, their presence having been discovered accidentally on roentgenologic examination on account of a fracture The fracture is therefore not a true one but a pathologic fracture. The symptoms are often grouped according to the grouping of the osseous lesions; that is, there may be pains in one leg and foot, one arm and hand and headache.

The symptoms of hyperthyroidism may develop at an early age.

Female patients who have osteitis fibrosa disseminata often exhibit sexual precocity. Catamenia may be established irregularly at an early age; in some instances before the age of 5 years The breasts develop and pubic and axillary hair appears. Synchronous with the sexual precocity is an associated skeletal and somatic precocity. During childhood these patients grow rapidly and are large for their chronologic ages, but growth ends before a large size is attained, owing to early closure of the epiphyses

EXAMINATION. These children are large for their age. If adulthood has been obtained, the patient is short of stature. The pigmented areas are present over an extremity in which lesions and fractures of bones are present The forehead is often prominent As stated, in female patients the breasts are well developed, and pubic hair and axillary hair are present during childhood The thyroid gland often is easily palpable.

Involvement of the upper ends of the femora often results in outward bowing, which in the presence of the bone disease predisposes to recurring fractures and pseudarthroses

Roentgenologic examination reveals osseous lesions characteristic of polyostotic fibrous dysplasia These lesions are usually confined to one side of the body except in the skull, where there may be a bilateral thickening of the bones at the base with obliteration of the frontal and sphenoidal sinuses The bone age is greater than the normal or actual age of the patient

The basal metabolic rate is often increased. Serum calcium, serum phosphorus, and serum alkaline phosphatase are usually within normal limits of concentration In these precocious girls the values for 17-ketosteroid urinary excretion and follicle-stimulating hormone are within the range of values for adult menstruating women In boys or men who have the disease, hormone disturbances have not been described

DIAGNOSIS The history, the physical examination and the presence of extensive osseous lesions which show an increased density on roentgenologic examination are sufficient for a diagnosis

Postmenopausal Osteoporosis. Between the ages of 40 and 60 years osteoporosis occurs almost exclusively in women It has therefore been assumed that the osteoporosis which develops in the 40 to 60 year age group may well be closely related to postmenopausal (endocrine) processes.

The assumption that osteoporosis in women more than 45 years of age is related to the postmenopausal syndrome is based on the proved influence of estrogenic hormones

adult rickets is justified. In both conditions the osteoporosis as revealed by roentgenologic examination is definite and sometimes of an extensive degree.

ENDOCRINE DISTURBANCES OF BONE

Disorders of the endocrine glands may profoundly affect the formation and the maintenance of bones Of these hormonal disorders the work of Albright has revealed that hyperparathyroidism is the most spectacular example.

Osteitis Fibrosa Cystica of Hyperparathyroidism. This bone disease is characterized by severe bone pains; generalized osteitis fibrosa; skeletal softening, with spontaneous fractures, angular deformities of the bones, and cysts and cystic tumors of the bones. The tumors are often referred to as giant cell tumors. There are an increased concentration of calcium in the presence of decreased concentrations of inorganic phosphorus and an increased concentration of alkaline phosphatase in the serum. There is an increased urinary content of calcium and phosphorus. In these patients bilateral renal stones and disturbed renal function may be present. The disease occasionally is accompanied by muscular hypotonia, fatigue, polyuria, palpitations and dyspnea. Nausea and vomiting are common. The bone changes are easily demonstrated by roentgenographic examination.

On examination tumors may be found in the jaw, metacarpals, metatarsals and at the ends of long bones. Bone deformities include bending of the long bones, deformities of the pelvis similar to those seen in osteomalacia, and various deformities of the vertebrae. A result of the vertebral changes is a decrease of stature, a pigeon-breast deformity of the thorax, and a disappearance of the neck into the thorax. The bones in this disease are more brittle than in osteomalacia, and fracture rather than bend The patient may be first examined for a recent fracture

Diagnosis of osteitis fibrosa cystica can be established on roentgenologic examination by the presence of a generalized decalcification and the even ground-glass appearance of the skull, cysts and tumors. A cortical "cyst" is most suggestive of hyperparathyroidism. The teeth fail to show any decalcification and therefore contrast markedly with the decalcified bones of the face The diagnosis is confirmed by the presence of hypercalcemia, hypophosphatemia and excessive urinary excretion of calcium.

Secondary Hyperplasia of the Parathyroid Glands and Bone Disorders. In this condition the parathyroid glands respond to the abnormal calcium and phosphorus metabolism rather than initiate it

Secondary hyperplasia of the parathyroid glands most commonly occurs in osteomalacia and in multiple myeloma and occasionally in generalized malignant metastasis in the bones Secondary hyperplasia of the glands may occur in children and in adults who have chronic renal failure with acidosis. The renal lesion seems to be one of the lower nephron type The disease is much more frequently present in those who have congenital lesions of the kidneys and changes in the skeleton.

The bone lesions present under these circumstances consist of osteitis fibrosa and are designated as *renal osteodystrophy* Occasionally a certain amount of bone deposit is present around the bone trabeculae in those who have chronic uremia. Despite the occasional occurrence of osteoid zones, the designation of renal rickets is not considered desirable by Snapper. He objects to the term renal rickets, even in children and young adolescents who have chronic renal failure, when the closure of [illegible] those of rickets

[illegible] lure

are hypocalcemia, acidosis and usually hyperphosphatemia. In instances of extensive parathyroid hyperplasia the calcium of the serum is often normal or *low normal* It seems possible that the secondary hyperplasia of the parathyroid glands is responsible for the change from the original hypocalcemia to a normal calcemia.

The thickening of the cortical and spongy tissue in some typical places such as the skull, ribs, vertebrae and femora may be so pronounced that macroscopic inspection discloses no difference between the cortex and the spongiosa. The long bones are characteristically clubbed in shape.

The symptoms are variable There is a retardation in physical development, but mental symptoms may or may not be present. Often optic atrophy and blindness are the first symptoms. Repeated bone fractures are characteristic. The head may be enlarged, probably owing to the thickening of the cranial bones as well as to a slight hydrocephalus.

On roentgenologic examination, bands running parallel to the line of the epiphyses may be observed in the bones of the hands and feet and in the metaphyses when there are only moderate degrees of calcification. In the scapulae, the ossa ilii, and the tarsal and carpal bones these bands are ring-shaped.

Biochemical tests reveal no signs of hyperparathyroidism The blood has normal values for calcium, inorganic phosphorus and magnesium. There is a normal number of units for (alkaline) phosphatase. The cellular elements of the blood are normal in the early stages of the disease. The absence of anemia has been regarded as an argument in favor of the conception that the osseous anomalies of marble bone disease are primary and not dependent on the damage of the bone marrow.

In favor of the diagnosis of marble bones is the presence of atrophy of the optic nerve associated with the tendency to bone fractures, malformation of the thorax, the thickening of the lower end of the femur, the peculiar shape of the head and deformed or incomplete teeth.

Chalky Gout (Tophaceous Gout). Chalky gout is a form of calcinosis, according to Rosenberg, characterized by deposition of calcium salts in the terminal phalanges of the toes. The mechanism by means of which the calcium is deposited is unknown The calcium concretions consist of calcium phosphate and calcium carbonate which usually are present in the same proportion as in bone. Small amounts of magnesium carbonate and phosphate, cholesterol and fatty acids also have been found in the deposits.

For a discussion of calcinosis, see Calcium in Chapter 22

Osteitis Deformans (Paget's Disease). Sir James Paget wrote, in part, of osteitis deformans:

"It begins in middle age or later, is very slow in progress, may continue for many years without influence on the general health, and may give no other troubles than those which are due to the changes of shape, size, and direction of the diseased bones.

"The disease affects most frequently the long bones of the lower extremities and the skull, and is usually symmetrical The spine, by change in its own structures, may sink and seem to shorten with greatly increased dorsal and lumbar curves, the pelvis may become wide, the necks of the femora may become nearly horizontal, but the limbs, however misshapen, remain strong and fit to support the trunk

"In its earlier periods, and sometimes through all its course, the disease is attended with pains in the affected bones, pains widely various in severity and variously described as rheumatic, gouty, or neurologic, not especially nocturnal or periodical It is not attended with fever No characteristic conditions of urine or faeces have been found in it.

walls, and not only the walls of their shafts, but in a very characteristic manner, those of their articular surfaces

"The outer surface of the walls of the bones was irregularly and finely nodular, as with external deposits or outgrowths of bone, deeply grooved with channels for the larger periosteal blood-vessels, finely but visibly perforated in every part for transmission of the enlarged small vessels Everything seemed to indicate a greatly increased quantity of blood in the vessels of the bone."

on calcium metabolism. The decreased production of estrogens during the menopause may result in decreased osteoblastic stimulation.

The symptoms of postmenopausal osteoporosis develop slowly. However, in some, skeletal deformities with a marked loss of stature may be present. The first symptom is often a sharp pain in the back after slight trauma. On roentgenographic examination of the spinal column a marked decalcification, particularly of thoracic and lumbar portions, is apparent. Atrophy of the bone is often so advanced that only the end-plates of the vertebrae are denser than the intervertebral disks. In the lumbar region, where the pressure is greatest in the center of the vertebrae, the osteoporosis causes the formation of fish or hourglass vertebrae. The elastic intervertebral disks expand, at the expense of the softened vertebrae, and often become wider than the vertebrae themselves. Ultimately a complete collapse of one or more vertebrae may occur In less advanced instances there may be present herniation of the nucleus pulposus.

Patients who have postmenopausal osteoporosis often show remarkable improvement after administration of testosterone propionate. However, actual recalcification of the osteoporotic bones rarely is observed.

Osteoporosis in Cushing's Syndrome. Cushing's syndrome may result from cancer or adenoma of the adrenal cortex, unilateral or bilateral hyperplasia of the adrenal cortex, or basophilic adenoma of the pituitary gland

In Cushing's syndrome the error in protein metabolism results in an inadequate repair of tissue, manifested by atrophy of the muscular system and an insufficient formation of bone matrix, and consequently osteoporosis. The osteoporosis involves the spinal column, pelvis and ribs. The intervertebral disks compress the bony part of the spinal column, and fish or hourglass vertebrae develop in the lumbar portion, while wedging of vertebrae is prominent in the thoracic portion In the later stages of the disease actual compression fractures of the vertebrae occur In more advanced disease the skull and the long bones become osteoporotic. In the calvarium the decalcification is localized mainly in the frontal and parietal bones

In the differential diagnosis hyperparathyroidism with osteitis fibrosa cystica generalisata, lipoid granulomatosis (eosinophilic granuloma, Hand-Schuller-Christian disease, xanthomatosis), and Recklinghausen's neurofibromatosis are considered

In those who have extensive involvement of the skeleton, secondary lesions may arise which are incompatible with prolonged life. The thorax may be so deformed that cor pulmonale is inevitable Pathologic fractures are common and usually heal well with the exception of those at the upper ends of the femora The endocrine disorder may be benign The skeletal lesions are usually benign Often there is little or no progression for a long time in the extent of the skeletal involvement.

Hypothyroidism. A characteristic of juvenile hypothyroidism is a retardation in osseous development with a resulting subnormal bone age as determined by roentgenologic examination. In addition to the retarded development there may be some abnormal ossification of the cartilages of the epiphyses and of the round bones.

DISEASES OF THE BONES ASSOCIATED WITH BLOOD DYSCRASIAS

Changes in the femora, tibias, fibulas and cranium of almost specific configurations occur during the course of some of the blood diseases such as Cooley's anemia. Osteoporosis too may occur during the course of a chronic anemia (see Chapter 12).

DISEASES OF THE BONES OF UNKNOWN ETIOLOGY

Marble Bones (Osteopetrosis). The disease, sometimes called also ivory bones and Albers-Schönberg disease, is often of familial occurrence (about 40 per cent of the cases). It may be hereditary

Complicating fractures may result from trifling causes.

PSEUDOFRACTURES

Pseudofractures are transverse zones of rarefaction varying in width from less than 1 mm. to more than 1 cm., over which there is a thickening of the periosteum. Pseudofractures affect various portions of the skeletal system and often are symmetrically distributed. They are generally an indication of certain weaknesses or dysfunction of the skeletal system

There are no signs or symptoms which may be said to be characteristic of pseudofractures. Pain is the commonest complaint, and may be an ache or may be most noticeable when pressure is exerted over an affected region. This is accompanied by a degree of limitation of function due in part to the pain elicited and in part to the subjective sensation of giving way of the affected bone. When the leg and the pelvis are involved, there may be a waddling gait similar to that found in congenital dislocation of the hip and coxa vara The patient may have the greatest difficulty in climbing stairs or in rising from the sitting position, and may show a definite hesitation in beginning to walk The reflexes may be abnormal, as a result of the disturbances in prolonged dysfunction of the calcium-phosphorus metabolism

The diagnosis is made roentgenologically.

TUMORS OF THE BONES

Bone tumors are classified as benign or malignant neoplasias.

Benign Tumors. Meyerding classified benign bone tumors as follows: (1) osteoid osteoma, (2) benign osteogenic tumors which occur as (a) osteoma or exostosis and (b) chondroma, (3) benign fibroma; (4) benign giant cell tumors, (5) benign vascular tumors of bone (angioma) Also included in this category are the lymphangiomas and the fibrosis secondary to these processes; (6) bone cysts; and (7) epiphyseal chondromatous giant cell tumor (Codman's tumor)

1. ***Osteoid Osteoma.*** An osteoid osteoma is a small, benign neoplasm of bone consisting of osteoid tissues carried by a substratum of vascularized osteogenic connective tissue It occurs most frequently in boys and young men, but it may occur throughout middle age. The tumor is commonest in the tibia or femur but may occur in other parts of the skeleton The etiology is unknown

The first symptom is pain. In the beginning mild and vague, it progresses in severity and constancy and may be described as a boring, localized pain It is worse at night than during the day If the lesion is near a joint, there may be limping from the stiffness, and weakness and pain on even limited motion Often when the patient first consults a physician, the symptoms have been present for less than 6 months; sometimes, from 6 months to 2 years.

There is a localized tender point, and often a tumor in the painful area. Disuse atrophy of adjacent muscles and increase in joint fluid, simulating a primary arthritis, may be present.

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is established by histologic examination of the tissue obtained by biopsy or that removed at the time of operation

Osteoid osteoma is to be distinguished from solitary abscess, sterile abscess of Brodie, sclerosing nonsuppurative osteomyelitis, and syphilitic or tuberculous osteitis.

2. ***Benign Osteogenic Tumors*** (a) ***Osteochondroma*** (*Osteoma Exostosis*) An osteochondroma is a bony skeletal outgrowth with a cartilaginous cap. The tumor occurs most frequently in boys and in men less than 25 years of age The tumors arise near the ends of long bones at sites of tendinous attachments The growth is outward in the direction of muscle These are usually congenital tumors

ETIOLOGY. The etiology, as stated by Paget, is unknown. The disease is one of advanced life, setting in at any time after the age of 30 years.

PATHOLOGY. There is little to be added to the description of the pathology as this was originally made The gross changes consist of a general thickening and bowing of the long bones, both characteristics being in evidence throughout the shaft and in advanced stages involving the epiphyses as well. Not infrequently the bone is increased to twice its normal size. In all cases the bowing is in the nature of an accentuation of the normal curve together with a moderate degree of torsion. Actual lengthening also takes place. The normal ridges and prominences may be the first to show the hypertrophy. The normal markings of the bone are lost The outline is fairly regular but the surface is uneven and is broken by rather large osteophytic outgrowths. These modifications are particularly common to the tibia, femur, fibula, pelvis, humerus, radius, ulna and clavicle The skull is thickened in some cases to two or more times its normal thickness.

SYMPTOMS. The onset is insidious, the progress is gradual. The patient may be scarcely conscious of the disorder until his attention is directed toward the deformities by his family. The first symptom in some instances is pain. If there is no pain, medical advice is not sought until very late in the course of the disease.

The pain most commonly is situated in the legs over the front of one or both tibias and is dull and felt deep in the bones It occurs in all possible grades, from mere discomfort to actual paroxysms of lancinating character. It is worse at the end of the day or at night and especially after long standing and unusual fatigue. Pains in the skull are rare. Pain may be absent throughout the course of the disease. One of the most constant and severe symptoms is cramps in the muscles of the legs.

EXAMINATION. The muscles of the legs or arms, if the bone is affected, show atrophy and occasionally edema. Tenderness to pressure over the muscles may be present.

The most pronounced deformities are to be found in the legs No other condition except rickets in children gives such an extreme degree of curvature of the legs. So great may the bowing become that the legs are crossed and walking is almost impossible. The sensations and reflexes are normal.

The head appears enormous and seems to rest directly on the shoulders. The enlargement is confined to the calvarium, which is symmetric but has a tendency to irregularities of the surface. Especially great hypertrophy of the supra-orbital portion of the frontal bone and the malar processes gives to the skull a massive appearance

The trunk often appears small and the thorax is compressed laterally Immense increase of the anteroposterior diameter accompanies the decrease in the lateral diameter The whole thorax is rigid and in consequence the respiration is mainly diaphragmatic The scapulas may show similar changes The spinal column becomes bowed, with the most marked curve in the thoracic portion, and finally complete rigidity develops. The bones of the upper extremities seldom show very noticeable alterations. The pelvis is very broad and massive with abnormal flaring of the iliac crests.

DIAGNOSIS' The diagnosis can be made in the advanced instances of the disease from the history and examination. However, the diagnosis is usually made by the roentgenologist from films made for causes other than bone diseases. The disease thus is often discovered before there are symptoms. When the disease is progressing rapidly there is increased concentration of calcium and of phosphates in the urine. The serum phosphatase is greatly increased in Paget's disease. The effect of immobilization results in a decrease of the alkaline phosphatase in the serum and the ... d phosphates in the urine

... nt disease of the bone
... gist. The diagnostician
... ation of ordering deep

5. ***Vascular Neoplasms of Bone. Benign Angioma.*** (a) *Hemangioma* may form in periosteum or marrow, usually in vertebrae or skull or in soft tissue where it may cause bone destruction. The tumor occurs in young adults and has no sex preference. It may be present, particularly if situated in a vertebra, in middle-aged patients.

Often there are no symptoms. When a hemangioma is situated in a vertebra, pain may be localized or may extend to the anterior part of the thorax, abdomen or down the leg

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation The preferred treatment is irradiation when lesions are inaccessible (as in vertebral bodies) or too large to excise.

(b) *Lymphangioma* was recorded by Bickel and Broders as causing almost complete destruction of the ilium from the sacro-iliac joint to the acetabular region. These lesions occur in the vertebrae. They may occur in other bones.

6. ***Bone Cyst.*** Bone cyst occurs most frequently in the metaphyseal regions of long bones, particularly in the upper ends of the humerus and the femur; these account for about half of the cases Other bones involved are the distal part of the radius, proximal part of the fibula, distal part of the ulna, and the phalanges of the hand or foot, ribs, pubis and ischium Latent bone cysts, recognized in adult life, may be present in the middle third of the shaft of the humerus and the femur. Bone cysts are commoner in boys and young men than in older men or in women They may be present in middle-aged patients.

Often there are no symptoms. When symptoms are present, they consist of mild pain, usually felt after prolonged use or strain of the part. A pathologic fracture may be the first manifestation. Trivial injury causing fracture of a long bone near a joint suggests the presence of a bone cyst.

A swelling may be palpated in the upper part of the tibia or in the lower part of the radius and ulna.

The clinical diagnosis is made on the basis of roentgenographic examination The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation

Healing of the pathologic fracture may heal the cyst.

7. ***Epiphyseal Chondromatous Giant Cell Tumor*** (*Codman's Tumor*) This tumor occurs in the upper end of the humerus in the region of the tuberosities, in the lower part of the femur, upper part of the tibia, and in the metacarpal and astragalus bones, more commonly in boys and young men than in older men or in women. The lesion is said to arise in the epiphysis and extend into the neighboring metaphysis, but it is never situated exclusively in the metaphysis

Pain, occasionally swelling, and limited motion in the adjacent joint are the symptoms There may be tumor at the site of pain.

The clinical diagnosis is made on the basis of roentgenographic examination The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation

Malignant T[illegible] [illegible]
diverse compone[illegible]
osteoblastic or [illegible]
sarcoma Those arising from the connective tissue of the bones are fibrosarcoma; from the cartilage, chondrosarcoma, from the vessels, hemangio-endothelioma; from the bone marrow, myeloma Those arising from the reticuloendothelial cells are termed either reticulum cell sarcoma or lymphosarcoma; and those from fat are liposarcoma

Osteogenic Sarcoma. Osteogenic sarcomas are complex structures. Only the well-trained histologist can differentiate between the various types of these tumors. The histologists cannot always agree among themselves on the diagnosis of the same histologic specimen.

There are often stiffness and limping which may have been present from 1 to 4 years. A bursitis may be the presenting symptom. Acute symptoms of pain, swelling and vascular compression may be due to an increased growth incident to malignant change.

Inspection and palpation reveal a firm, painless, bulging juxta-articular mass over which soft tissues move freely. Pain and fluctuation may be found with bursitis

The clinical diagnosis is established by roentgenographic examination. The final diagnosis is established by histologic examination of the tissue removed for biopsy or that removed at the time of operation.

(b) **Chondroma.** Chondromas occur in the small bones of the hands and feet, spinal column, pelvis, ribs and sternum in patients from the age of 10 to 30 years.

Rickets, trauma, differentiation of prechondral connective tissue or cartilage cells, and supernumerary joint cartilages derived from prechondral connective tissue are some of the possible etiologic causes

The tumors may become large before symptoms appear However, after tumor formation there may be aching pain, deformity and, frequently, pathologic fractures The tumors may be present for years without causing symptoms.

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is established by histologic examination of the tissue obtained for biopsy or that removed at the time of operation

3 ***Fibroblastic Tumor. Benign Fibroma.*** Benign fibroma, or nonosteogenic fibroma of bone, occurs in the shaft of a long bone, usually with 1 or 2 inches (about 2 5 or 5 cm) of unaffected shaft between the lesion and the nearer epiphyseal plate. These tumors may occur at any age or in either sex

Often there are no symptoms However, there may be tenderness and swelling with pain and stiffness in the adjacent joint

The clinical diagnosis is made on the basis of roentgenographic examination The final diagnosis is established by histologic examination of the tissue obtained for biopsy or that removed at the time of operation.

4. ***Giant Cell Tumors*** *(Osteoclastoma)* Benign giant cell tumors occur in long bones, principally in the tibia, femur or radius They arise in the epiphysis and progressively invade cancellous bone They occasionally present eccentrically and are called subperiosteal giant cell tumors Growth is limited by periosteum and articular cartilage They occur from the age of 10 to 40 years and have no sex preference

Trauma seems to be important There is subcortical or subperiosteal hemorrhage with subsequent atypical repair of avascular cortical bone

Pain may begin as an intermittent, mild, dull ache made worse by activity and diminishing or disappearing during rest Swelling is often present but it is not an early symptom When there are marked expansion and destruction of bone, there is pain Movement of the adjacent joint may be limited

Palpation often elicits tumor and tenderness. Pathologic fractures are common These fractures are suggested by sudden pain, altered contour and increased swelling. Recurrences after operation occur. Malignant degeneration was present in 19 per cent of Meyerding's patients

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation.

Bone cysts occur in the diaphysis before the adjacent epiphysis closes and are to be differentiated from benign chondroblastoma; from the lesions of hyperparathyroid disease of bone, which occur in the shaft, are multiple, and are associated with altered blood chemical findings; and from central chondroma, myeloma and medullary osteolytic type of osteogenic sarcoma.

Accessible lesions are treated surgically. There are many physicians, however, who advocate primary irradiation, believing that better function is maintained and operation avoided.

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation.

The prognosis is always grave; only 15 per cent of patients live 5 years The usual course in the fatal instances averages about 14 to 15 months. Those patients usually receive surgical treatment.

2. ***Secondary Chondrosarcoma.*** This cartilaginous malignant tumor originates in a benign lesion. The benign tumors thus affected include cartilaginous exostosis, central chondroma, hereditary deforming dyschondroplasia and Paget's osteitis deformans

Secondary chondrosarcoma occurs more frequently in men between the ages of 35 and 55 years than in men of other ages or in women. The most frequent sites of occurrence are the lower end of the femur and upper end of the humerus. The tumors may appear about the ribs, in the region of the heel, or in the pelvis

There is a history of an injury, a swelling which has persisted, or the patient may state that there has always been a deformity in the region in question After a number of years the swelling increases in size and pain is present A pathologic fracture occurs occasionally.

Aside from the presence of the tumor, and perhaps some limitation of the adjacent joint, the results of examination are negative

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation

The life expectancy after the development of a secondary chondrosarcoma varies from 2 to 10 years The majority of patients who have been reported as cured have been treated by radical resection or amputation and not by curettage, cauterization or roentgen rays.

Endothelioma (*Ewing's Tumor*). The nature of this tumor is strongly suggestive of an infection The patient exhibits a generalized systemic reaction with fever and leukocytosis The histologic appearance is said to resemble that of an inflammatory lesion The disease is largely limited to the white races though it has been recorded in Negroes. There is a preponderance of incidence among males.

The tumor occurs most commonly in the femur and the tibia, and elsewhere in the following order of frequency in the pelvis and ribs, the clavicle, scapula, humerus, radius and ulna, lumbar and cervical vertebrae and the skull.

The symptoms commence with pain which is variable in intensity, usually intermittent, becomes increasingly more severe, and is commonly worse at night than during the day. The lump or swelling in Ewing's tumor is present by the time there is pain, and in about one fourth of the cases may be present before there is pain. Fever is a common symptom and is of the intermittent spiking type. The temperature is usually of the range between 99 and 101 F (37.2 and 38 3 C).

Spontaneous remissions occur with a decrease in the size of the tumor, less pain, and lack of fever, only for the symptoms to return again In some cases the course is rapid The average life expectancy is less than 2 years

In a few of those who have this tumor the symptoms may have been such that the patients are operated on for incision and drainage of abscesses

The swelling is tender, usually fusiform in shape, and further mimics an infection with increased local heat and dilated overlying veins. These tumors are further removed from the articulations than many other bone tumors and hence the disability is a less constant feature as an early symptom.

Leukocytosis is fairly constant; the leukocyte count is in the range from 10,000 to 20,000 per cubic millimeter of blood The differential blood count is not characteristic, it is not unusual in any way. Anemia is not an early finding Endothelioma metastasizes to other bones, to the lungs and to the lymph nodes and viscera.

The clinical diagnosis is made on the basis of roentgenographic examination.

Osteogenic sarcoma is essentially a disease of youth, the majority of the patients being less than 30 years of age. The tumor occurs more commonly in females than in males.

Osteogenic sarcoma characteristically is situated in the lower extremity in the region of the knee. However, it may occur in the metaphyseal ends of any of the long bones It does not occur in the shaft or the epiphysis.

Pain is the first symptom. In the beginning it may be intermittent or transient. As the tumor enlarges, the pain is continuous, boring, persisting, and worse at night than during the day.

The tumor is usually ill-defined and diffuse in the early stages; later there is a definite mass firmly attached to the underlying bone. The consistency varies greatly, depending on the type of sarcoma. The sclerosing osteogenic sarcoma is characteristically of bony hardness; the osteolytic type is less firm in texture.

As the tumor increases in size, the skin becomes shiny and stretched. Often there may be dilated veins in the region of the tumor and an increased surface temperature Increased heat of the tumor is often observed, especially in the more rapidly growing types.

Disability is produced by limitation of motion of the adjacent joint as the result of pain and tumefaction, but there is no actual involvement of the joint.

Leukocytosis and some fever may be present. The concentration of alkaline phosphatase in the blood serum is increased

The clinical diagnosis is established by roentgenographic examination The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation.

The five-year survival rates run consistently between 15 and 25 per cent. The prognosis in general is much poorer in young children than in older persons.

In general most orthopedists agree that amputation is the only treatment in attempting a cure and that all other methods are adjuncts or palliative

Fibrosarcoma. This tumor arises from the nearby soft tissues or possibly from the connective tissue structures of the periosteum. The femur and tibia are the commonest sites. The upper extremity is involved to a less extent than the lower extremity The skull and pelvis may be involved.

Fibrosarcoma occurs infrequently. It tends to affect adults who are more than 30 years old

The first symptom is pain, which develops slowly over months. As time passes, there is a swelling and then limitation of movement of the affected part The swelling is deep, attached to the underlying bone, and most commonly is of a semisolid consistency Occasionally, but a distinctive feature when present, the tumor will cross a joint and involve a second bone. The lymph nodes may be enlarged These tumors metastasize by the blood stream, usually to the lungs.

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis is established by histologic examination of the tissue obtained for biopsy or that removed at the time of operation.

The prognosis of this tumor is better than that of the osteogenic sarcoma. The tumor is radioresistant. Surgical removal is the preferred treatment

Chondrosarcoma. Some chondrosarcomas are benign, while others are known to be malignant from the start and are called primary chondrosarcoma or chondroblastoma

1. ***Primary Chondrosarcoma.*** The primary chondrosarcoma occurs in young persons less than 30 years of age, with the greatest incidence in patients between the ages of 14 and 21 years. The sex ratio is about the same as in the osteogenic sarcomas; that is, 2 males to each female.

The commonest situations are the lower end of the femur, upper end of the tibia or upper end of the humerus' The symptoms and the findings on examination are the same as those of osteogenic sarcoma.

The leukocyte count is normal. True myeloma cells may be present. Numerous plasma cells may be observed and if so the disease may be termed a plasma cell leukemia. The platelet count is usually normal. Failure of the clot to retract and difficulty in obtaining serum are often experienced by the laboratory technician Viscosity of the blood is often greatly increased. The concentration of plasma protein may exceed 10 0 gm. per 100 ml The increase is due mainly to the globulin fraction, and the albumin-globulin ratio is reversed.

The serum in multiple myeloma may be anticomplementary. The concentration of serum calcium is often increased (12 to 16 mg. per 100 ml.) but, in contrast to the finding in generalized osteitis fibrosa cystica (except in the terminal stages when renal failure is extreme), the inorganic serum phosphorus is normal in amount or may even be increased The uric acid content of the blood may be increased to 25 or 30 mg per 100 ml

The urine often contains albumin and casts Bence Jones protein appears in the urine occurring in 6 of each 10 who have multiple myeloma It should not be regarded as characteristic of multiple myeloma, for Bence Jones protein occasionally *occurs in the urine of leukemic patients and polycythemic patients and in those who* have diffuse metastasis to the ribs; for instance, in carcinoma of the thyroid gland. The consensus is that the excretion of Bence Jones bodies in the urine is specific for some pathologic process situated in the bones that contain red marrow. In the presence of very high concentrations of serum proteins, the Bence Jones protein may be absent from the urine owing to an inability of the kidney to excrete it. A failure to concentrate the urine and retention of nitrogen may develop.

The *bone marrow* contains myeloma cells

The diagnosis is made on the basis of (1) the presence of Bence Jones bodies in the urine, (2) the roentgenologist's report of myeloma or metastasis, (3) increased plasma proteins (8 gm or more per 100 ml of blood), (4) difficulty encountered in making of the blood smears—rouleaux formation of the erythrocytes Despite the prolonged course, the prognosis is ultimately unfavorable

Reticulum Cell Sarcoma. Reticulum cell sarcoma is considered a primary bone tumor in that it arises from the parts of the reticuloendothelial system which are found in bone It may resemble histologically an ordinary reticulum cell lymphosarcoma which has metastasized to bone

This tumor has been considered to be the same as Ewing's sarcoma It occurs in an older age group than Ewing's tumor, however, being found in early adulthood. It occurs more frequently in men than in women

Reticulum cell sarcoma occurs primarily in the metaphyseal regions of the long bones but may involve the flat bones also

Pain is the primary symptom A tumor which is tender may be present. There is no fever, nor is there leukocytosis.

The clinical diagnosis is made on the basis of roentgenographic examination The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation The outlook is more favorable than in Ewing's tumor This tumor is radiosensitive

Liposarcoma. The revised bone sarcoma registry of the American College of Surgeons includes liposarcoma as a malignant tumor which may be primary in bone This tumor is rare

The tumor is commonly found in the soft tissues Its existence as a primary tumor of bone is doubtful Liposarcoma of bone, as well as of any other part of the body, tends toward multiple lesions

The clinical diagnosis is made on the basis of roentgenographic examination. The final diagnosis depends on findings on histologic examination of the tissue obtained for biopsy or that removed at the time of operation

Secondary Malignancy of Bones (Carcinoma). Metastatic malignancy to the bone is carcinoma from organs and tissue of epidermal origin, such as the digestive

The final diagnosis is made on the basis of histologic examination of the tissue obtained for biopsy or that removed at the time of operation.

An outstanding feature of Ewing's tumor is that the original lesion responds to roentgen therapy. Despite the radiosensitivity of the primary lesion, metastatic lesions nearly always develop and they are usually more resistant to treatment than the primary lesion. Surgical treatment offers no better prognosis than does roentgen therapy.

Multiple Myeloma. Myeloma involves the bones of the skeletal trunk, producing pain and resulting in pathologic fractures and anemia. The disease is often distinguished by the excretion of Bence Jones protein in the urine and its accumulation in the blood However, the presence of Bence Jones protein in the urine is not diagnostic, for it does not occur in the urine in more than 6 of each 10 who have the disease

The etiology of multiple myeloma is unknown. The disease often appears after the age of 40 years It is at least twice as frequent in men as in women.

Pain, tumors, deformity, pathologic fractures and neuralgic or neurologic symptoms are the commonest complaints, and one of these may be the basis of the presenting complaint Less frequently, complaints referable to anemia or abnormal bleeding or symptoms suggesting nephritis come first.

The *pain* is wandering and intermittent, and it is referred to the back, less often to the thorax or the extremities. Girdle sensations, or extension down the legs may be present Generally the onset of pain is related to motion or pressure. The pain may be extremely severe and may last for hours or days but intermittency and even remissions for several months are common The disease is often accidentally discovered by finding the Bence Jones protein in the urine or by evidence revealed in roentgenograms made for other diagnostic purposes.

Gastrointestinal symptoms are rare but have been described as diarrhea, colicky pains, nausea and vomiting Hematemesis and melena have been described Epistaxis may occur and ecchymosis, bleeding about the gums and lips, and petechiae may be present in some of these patients.

Intravascular thrombosis may occur. Chronic bronchitis and pulmonary emphysema are common complications of the thoracic deformity in aging patients but are not symptomatic of multiple myeloma The liver, spleen and lymph nodes are not enlarged

There may be evidences of loss of body weight. The tumors are multiple and usually confined to the ribs, sternum, spinal column, clavicles, skull, or to the extremities about the shoulder girdle or the pelvic girdle Generally the swellings are small, the larger ones not more than a few centimeters in diameter. The tumors are elastic, often yielding a distinct crepitation on palpation. Single palpable lesions may occur, but the roentgenogram will reveal the presence of more than the one palpated. Pathologic fractures are frequently present and discovered on roentgenographic examination Thoracic deformity is common

Paraplegia due to compression of the spinal cord, intercostal neuralgia, radiculitis, diplopia, anisocoria and failing vision, or complete blindness due to thrombosis of the central artery of the retina, as well as other neurologic syndromes, may be observed with multiple myeloma as their cause.

Extra-osseous tumors may be present in the testis or in the tonsil Pain in these tumors is absent if the skeleton is not involved.

Anemia is of only a moderate degree if present at all Enumeration of the erythrocytes is difficult, owing to clumping The clumping of the erythrocytes is related to the increased quantity of globulin in the plasma which causes a marked tendency to clumping and to rouleaux formation. Clumping and rouleaux formation may prevent the making of satisfactory blood smears. Blood grouping may be difficult and the serum may need to be warmed or diluted before a satisfactory test can be made. Of course, the sedimentation rate of the erythrocytes is increased.

and postoperative convalescence. It seems that irrespective of the changes in the blood or the vessel walls the essential element in the production of arterial thrombosis is slowing of the blood flow.

SYMPTOMS. Numbness, coldness and tingling, and loss of muscular power of the affected extremity are the most constant symptoms. Pain is inconstant in sudden arterial occlusion. It is present in only one half of those patients who have this misfortune. Pain when present is usually severe.

As has been stated, sudden arterial occlusions often occur during the course of a severe illness The general symptoms of the primary disease may mask those of the vascular accident. If the primary disease is mild, a sudden arterial occlusion may be manifested by tachycardia, profuse perspiration, and anxiety and pain.

EXAMINATION. There is absence of a pulse in the artery distal to the occlusion. There are coldness, a partial loss of sensation, and for a short time after the occlusion, vasodilatation

After a sudden arterial occlusion there may be present gangrene or ischemic neuritis. When a large artery, such as the femoral, is affected, usually an extensive gangrene ensues which involves the leg and the foot In instances in which the lower part of the aorta is involved, there are severe pain and complete ischemia and paralysis of one leg or [illegible]
the lower extremity by [illegible]
may involve digits only [illegible]
followed by ischemic neuritis or a state of chronic arterial insufficiency Subsequent arterial occlusions are to be expected

Ischemic neuritis is common among diabetic patients, and it may merge with the so-called true diabetic neuritis Ischemic neuritis occurs most commonly when the occlusion is nearer the aorta The pain of ischemic neuritis, like pretrophic pain, results from a lack of blood flow to the part It is characterized by having the distribution of the peripheral nerves It may occur with or without ulceration or gangrene. If there is ulceration or gangrene present, the pain of ischemic neuritis extends proximally from these processes Muscular weaknesses and reflex disturbances may follow the ischemic neuritis

DIAGNOSIS. A cold pulseless extremity is diagnostically a definite entity.

The prognosis as to life is poor when simple arterial thrombosis develops in the arteries of the extremities in the course of infectious diseases or congestive heart failure.

Traumatic Arterial Thrombosis. Penetrating wounds and severe blunt trauma may result in bruising or crushing of the wall of the artery with subsequent thrombosis. The prolonged use of a crutch may cause thrombosis of the axillary or brachial artery. Cervical ribs have caused thrombosis of the subclavian artery. The symptoms and findings of acute traumatic arterial thrombosis are those of acute arterial occlusion.

Arteriosclerosis and Arteriosclerosis Obliterans. ***Arteriosclerosis.*** The etiology of arteriosclerosis is not known The consensus is that the mechanical theory and the metabolic theory are the outstanding ones in regard to the cause and development of arteriosclerosis

The advocates of the mechanical theory see the arteries change in texture as the result of continual pulsations as the years pass This change in the texture of the arteries constitutes arteriosclerosis, which reaches its most extensive development in old age. The mechanical theory is not hampered by the fact that manifestation may begin in young [illegible]

The metabolic theory of the development of arteriosclerosis is based on defects in lipoid metabolism It is assumed that if atheromas contain quantities of lipoid material, [illegible]bolism is at fault This theory does not seem to be hampered by the fact

tube and endocrine glands. These malignant metastases are described in various parts of this book in the descriptions of the organs affected by the primary malignant focus. Sarcomatous metastasis to bone is less frequent.

DISEASES OF PERIPHERAL VESSELS AS THEY AFFECT THE EXTREMITIES, OTHER PARTS OF THE BODY AND LOCOMOTION

Anomalies of Peripheral Blood Vessels. Anomalous situations of peripheral blood vessels are often present, and these seem to originate from the choice of unusual paths selected by the developing primitive vascular plexuses. Other reasons for abnormally situated vessels may be the persistence of vessels which are normally obliterated, and the disappearance of vessels which normally persist Incomplete development fusions and absorptions of parts, usually distinct, may add to the difficulty in trying to find a peripheral pulsation which ordinarily has a definite situation.

Manifestations of Diseases of Peripheral Blood Vessels The presence of disturbances of the peripheral circulation is often made known by pain which is induced by exercise and relieved by rest, influenced by posture, localized to one digit or to a part or all of an extremity Often the pain is accompanied by color changes, and both are paroxysmal in occurrence and are influenced by elevation and dependency of the part Excessive cold or warmth of extremities together with abnormal pulsations in the arteries or enlarged veins may accompany the color changes and pain There may be present ulceration, gangrene, scleroderma, impaired nail growth, excessive calluses or paronychial infections and an enlargement or a smallness of extremities

The examination of the extremities of patients who are suspected of having peripheral vascular disease can be performed quickly The examiner, according to Allen, Barker and Hines, must answer the following questions in order to complete the examination. (1) Is swelling, atrophy, elongation or shortening of the limbs present? (2) Is ulceration, gangrene, scleroderma, eczema, varices or thrombophlebitis present? (3) Is the temperature of the skin abnormal? (4) Is the color of the skin abnormal? Do elevation and dependency of the extremities cause unusual discoloration of the skin? (5) Are pulsations in the peripheral arteries impaired? (6) Is there auscultatory evidence of arteriovenous fistula or aneurysm? If the answer to all these questions is "No," all peripheral vascular disease except Raynaud's disease and erythermalgia may be excluded. If the answer to any of these questions is "Yes," more detailed examination and analysis may be advisable

The more technical and detailed examinations comprise (1) tests of capacity of blood flow (vascular function tests) in skin as shown by vasodilatation, by reflex heat, artificial fever, anesthesia (local, general, spinal, and paravertebral), intradermal histamine and saline injections, and reactive hyperemia, (2) tests of capacity for blood flow (vascular function tests) in muscle, by walking certain distances and by ergographic measurements of muscle fatigue, and (3) test of the functional state of the vessels, by oscillometry and roentgenologic studies, especially by diodrast injection of arteries or veins Judgment, much experience and common sense are needed for proper appraisal of these special tests.

Arterial Thrombosis. *Simple Arterial Thrombosis.* In an occasional instance an occlusion of a peripheral artery may occur in the absence of disease of the endothelium of the artery and without a history of injury of the vessel. There is no evident source of the arterial embolus In those who have such an arterial occlusion, often there is a slowing of the blood flow, or a change in the contents of the blood, or both may be present.

The blood flow is slowed during starvation, severe infections and in polycythemia vera and at times in minor degrees of arteriosclerosis, congestive failure in heart disease,

arterial insufficiency; within 30 seconds, a marked degree; and within more than 60 seconds, an extreme degree.

In arteriosclerosis obliterans there are more or less constantly the following findings: a lower skin temperature of the foot or toes than of other parts of the body, often scarring and shrinkage of the digits, impairment of nail growth; paronychias which heal slowly, and ultimately may develop into gangrenous or ulcerative lesions often involving the bone of the affected digit.

Ulceration and gangrene of arteriosclerosis obliterans are of the dry type and are accompanied by little or no systemic reaction. When diabetes is present, the lesions may be of the moist type and there may be considerable systemic reaction with rapid development of lymphangitis and often septicemia.

In advanced stages of arteriosclerosis obliterans there is atrophy of the muscles of the leg, absence of subcutaneous fat, atrophy of the skin, and often osteoporosis.

Roentgenograms are of definite value in the distinction of arteriosclerosis obliterans from other types of occlusive arterial disease. Roentgenograms are made of the leg, the thigh and pelvis, and often lateral views of the lumbar region are taken to detect calcified arteries However, calcified arteries which are revealed by roentgenographic examinations may not prove or indicate occlusive vascular disease.

DIAGNOSIS. Intermittent claudication is almost pathognomonic of occlusive arterial disease, but it is not always present

The diagnosis of arteriosclerosis obliterans is made on the basis of the absence of pulsations in one or both of the posterior tibial or popliteal arteries and unequal postural color changes in the two extremities. The presence of all of the other symptoms and findings is confirmatory evidence of the disease. Roentgenologic examination may reveal visible calcification in the walls of the vessels.

In general, arteriosclerosis obliterans is a progressive, degenerative vascular disease.

Thromboangiitis Obliterans (Buerger's Disease) Thromboangiitis obliterans is a segmental, inflammatory, obliterative disease of the arteries and veins of the extremities of young men In rare instances the disease may affect the viscera

Thromboangiitis obliterans resembles an inflammatory vascular disease. The consensus is that the use of tobacco is an important etiologic factor

The lesion of thromboangiitis obliterans is a segmental, inflammatory, nonsuppurative panarteritis or panphlebitis with associated thrombosis without necrosis of the wall of the vessels

SYMPTOMS Intermittent claudication is the first symptom in more than 7 of every 10 who have the disease Once intermittent claudication is present, it will remain present for the remainder of the life of the patient It occurs most commonly in the arch of the foot or in the calf of the leg distal to a point of demonstrable arterial occlusion Intermittent claudication is an ache, sense of fatigue, persistent cramp or severe aching, squeezing pain It occurs only after exercise of the affected muscles and is relieved promptly by rest without change of position.

Often as a first symptom some of the digits of a foot or hand may feel abnormally cold on short exposure to a cold environment. Often there is an associated sensation of numbness or other paresthesias

Pretrophic or rest pain may persist for hours, it is more severe at night than in the daytime and may be premonitory of ulceration or gangrene. The pain of ischemic neuritis is severe, paroxysmal and widespread, and is associated with various paresthesias The pain of ulceration and gangrene is localized and is situated in the region adjacent to ulcers or gangrenous tissue The pain of osteoporosis and atrophy is associated with weight bearing or pressure

The lesions of superficial thrombophlebitis, which occur in thromboangiitis obliterans, are usually painful but the pain is not severe. It persists until the lesion involutes, and then gradually disappears

that although extensive arteriosclerosis increases with age, there is a tendency to a decrease of concentration of blood lipoids as age advances

Disorders of lipoid metabolism manifested by lipemia often are accompanied by severe atherosclerosis The presence of diabetes mellitus is accepted as a predisposing factor to severe and premature arteriosclerosis, atherosclerosis and arteriosclerosis obliterans

Arteriosclerosis Obliterans. Arteriosclerosis obliterans, as it occurs in the extremities, is the result of an obstruction of the blood flow through large arteries to a sufficient degree to result in ischemia of the tissues of the extremities. A slowly developing occlusion may be better compensated for than the rapidly developing ones

SYMPTOMS In a slowly developing arteriosclerosis like arteriosclerosis obliterans intermittent claudication is the first symptom. The pain may be present in one leg or both legs, for instance in the foot, in the calf or in the thigh, and occasionally in the hips and lower part of the back. In the majority of patients, however, claudication is present only in the calf muscles. The pain of claudication requires fatigue for its development. The pain appears while the patient is walking. It is sharp and shooting, darting, moving rapidly lengthwise of a group of muscles. The pain increases in severity with the continuation of walking. Rest affords prompt relief Immediately on relief of the pain exercise may be resumed. The distance that the patient is able to walk before the distress develops varies with the proximity of the arterial occlusion to the aorta The distance may vary from 20 to 25 steps to a mile or more If the pain of claudication is not yielded to, there is a gradual stiffening and tightening of the muscles which, when the disease is severe, may reach the point that the patient is unable to use the part because of muscle spasms which are too painful to be endured. After claudication there may be soreness, tenderness and rather prolonged fatigue

Pain commencing while the part is at rest is rarely the first symptom. This is a late symptom of advanced and severe disease Rest pain is always present if there is an acute arterial occlusion Night pain occurs in the toes, the foot and the lower part of the leg It is often a persistent aching, sufficient to interfere with sleep

Moderate to severe pain is associated with ulceration and gangrene Pretrophic pain, like rest pain, is usually worse at night than in the daytime. Pretrophic pain may be so severe that it is not controlled by the administration of opiates

When there is prolonged disuse of the joints, stiffness and even ankylosis may develop. At least a part of this joint stiffening is secondary to the muscular weakness characteristic of insufficiency of the peripheral circulation.

EXAMINATION On examination of a patient who has arteriosclerosis obliterans the findings are those of occlusive arterial disease. A decrease in the size of the pulsations in the peripheral arteries is present. The absence or impairment of pulsation in the dorsalis pedis artery is not necessarily significant Pulsations, though they may be very weak, are usually present in the posterior tibial, popliteal and femoral arteries when the patient is at rest in a warm environment.

The color of the feet is not changed until the arteriosclerosis obliterans is moderately advanced. When the disease is more severe, the toes of one or both feet or an entire foot are erythematous. Later the reddish color changes to a bluish discoloration or pallor. Immediately after an acute arterial occlusion the foot is pale and appears shrunken.

Postural color changes, such as pallor on elevation and a delay in a return of rubor on dependency, are pathognomonic of occlusive arterial disease. Some idea of the severity of the arterial insufficiency may be obtained as follows: If the feet are elevated for 2 minutes and then placed suddenly in the dependent position, failure of the color to return within 15 seconds indicates a moderate degree of

and nonvascular diseases. The vascular diseases to be differentiated are Raynaud's disease, acroscleroderma, livedo reticularis, acrocyanosis, erythermalgia or erythromelalgia, pernio, ergotism, acute thrombophlebitis of large veins, venous insufficiency and varicose veins.

The diseases which are not at least primarily vascular (nonvascular) which may require differentiation are frostbite, trophic ulcers and gangrene associated with organic disease of the nervous system, pronated feet, metatarsalgia and other mechanical derangements associated with the flatfoot syndrome.

The prognosis of thromboangiitis obliterans as to the loss of life or limb is difficult to estimate

Arteriovenous Fistula. The terms pulsating angioma, cirsoid aneurysm, arteriovenous aneurysm, varicose aneurysm, cavernous angioma, aneurysm by anastomosis, arteriovenous varix, aneurysma serpentina, angioma plexiforme, angioma arteriale, angioma arteriale serpentinum and angioma arteriale racemosum have been employed to designate or to indicate arteriovenous fistula.

Arteriovenous fistula most commonly is acquired, but it does occur as the result of congenital malformations

Congenital Arteriovenous Fistula. Congenital arteriovenous fistula results from failure of differentiation of the common embryologic anlage into artery and vein There is a persistence of the vessels or communications which are normal in the primary anlage.

Congenital arteriovenous fistulas occur anywhere in the body, for instance in the bones, cranium, middle ear and all of the parenchymatous organs. The only easily demonstrable congenital arteriovenous fistulas occur in the extremities.

SYMPTOMS OF ARTERIOVENOUS FISTULA IN THE EXTREMITIES. When varicose veins appear without obvious cause over a leg or an arm of a child, particularly when associated with ulceration or elongation of the limb, a congenital arteriovenous fistula is suspected. In some instances of congenital arteriovenous fistula the enlarged, varicose, tortuous veins may pulsate

Ulceration attributable to fistula may affect the hands, whereas chronic venous insufficiency attributable to ordinary varices or to thrombophlebitis is singularly absent from the hands

EXAMINATION Hemangiomas (birthmarks), cavernous or diffuse, port-wine color or bluish red, are present in somewhat more than half of those who have congenital arteriovenous fistula affecting the extremities. Associated with hemangiomas may be an increased growth of hair and increased sweating

Thrills and bruits are absent in congenital arteriovenous fistula Examination to establish the presence of an arteriovenous fistula includes analysis of the composition of the blood near the fistula Arterialization of the venous blood invariably occurs. For analysis the blood is withdrawn from a vein proximal to the fistula on the involved side and from a vein in a similar location on the normal side. The blood from the vein of the involved extremity has an oxygen saturation which varies from 5 to 45 per cent greater than that from the normal extremity.

Arteriography is performed after local anesthetization The contrast medium is ejected from the syringe into the occluded artery proximal to the site of suspected arteriovenous fistula A series of four or five arteriograms is made in rapid succession Demonstration of the opaque medium in the veins above the point of injection in the first arteriogram when the artery is closed by digital pressure is diagnostic of arteriovenous fistula The amount of filling of the venous trunks is proportional to the size of the fistula or fistulas Correct interpretation is made only by those experienced in the performance and in the interpretation of the results of arteriography.

DIAGNOSIS The diagnosis of arteriovenous fistulas of congenital origin depends on differences in oxygen saturation of the venous blood or on the results of arteri-

Allen, Barker and Hines separate cases of thromboangiitis obliterans into four groups on the basis of the clinical course: (1) In the *nonprogressive type, after one or two episodes of arterial occlusion further episodes fail to develop and a period of circulatory compensation follows which may last for many years. (2) A slowly progressive clinical course characterized by episodes of mild to moderate arterial occlusion which occur at long intervals apart Between episodes are quiescent periods of weeks to months, even years, when there is some improvement in the circulation as the result of development of arterial anastomoses. Finally the active lesions may cease to develop, and then the patient is left with a moderately to severely damaged arterial tree. (3) In some patients a sudden arterial occlusion of large vessels occurs and the result is extensive gangrene If gangrene does not supervene, convalescence is slow and severe arterial insufficiency persists. (4) Rapidly progressive or fulminating instances of the disease, with widespread gangrene necessitating amputation of the legs and perhaps some of the fingers, occur but are rare.

EXAMINATION The extremities may appear a normal color if the patient is in bed If the extremities are in a dependent position, they are often red or cyanotic

Asymmetric postural color changes frequently are found in thromboangiitis obliterans Raynaud's phenomenon may occur in association with thromboangiitis obliterans Affected parts become abnormally blanched after a short period of elevation, and on dependency after elevation there may be a delay of 5 to 60 seconds before the color returns to the skin and before the superficial veins again become visible. After the return of color the part usually becomes abnormally red

The pulsations in the posterior tibial and dorsalis pedis arteries are impaired or absent in the great majority of cases of thromboangiitis obliterans. Impairment or absence of radial or ulnar pulsations occurs in less than one half of those who have the disease. Impairment or absence of pulsations in the dorsalis pedis artery is present as the result of anomalies of the artery in 1 of every 10 normal persons Pulsations in posterior tibial arteries may be said never to be absent as a result of congenital anomalies

Ulceration and gangrene may occur spontaneously, but frequently they follow mechanical, chemical or thermal trauma The sources of trauma often precipitating gangrene are injury from nails in shoes, bruises, nicks or cuts in the skin from trimming nails and corns, or from other treatment of corns by freezing or burning, and the injudicious use of strong or irritating medicaments or chemicals Nail growth is slow The nails may be thickened or thinned and deformed The digits and sometimes an entire foot appear shrunken owing to the atrophy of the muscle and absorption of fat. The bones are osteoporotic on roentgenographic examination Gangrene of the hand or arm is rare.

Edema of the affected extremity or extremities is a common finding A red, cold, swollen foot with ulceration or gangrene of one or more toes is commonly seen in thromboangiitis obliterans Superficial thrombophlebitis in association with definite occlusive arterial disease is characteristic of thromboangiitis obliterans

DIAGNOSIS. A diagnosis of thromboangiitis obliterans is made when it is established that there is organic occlusion of peripheral arteries. In a young man the absence or marked impairment of peripheral arterial pulsations and the presence of asymmetric temperature and postural color changes of digits of the feet or hands are diagnostic. A dry gangrene of one or more digits which cannot be attributed to

livedo reticularis of the legs and (4) xanthoma tuberosum.

Thromboangiitis obliterans may have to be differentiated from a host of vascular

Raynaud's Disease and Phenomenon. Raynaud's syndrome occurs both as a primary disease entity and as a secondary result of a number of etiologic factors.

Primary Raynaud's Disease. The cause of the primary Raynaud phenomenon is not known The disease is peculiarly common in girls and women and usually begins about the onset of menstruation, although the first appearance may be as late as 35 to 40 years of age. It is frequently observed that more than one member of the family of the patient has suffered from cold hands or feet, "dead fingers" or other manifestations of vasospasm The importance of morbid heredity in this disease, however, has not been evaluated

Among the known contributing factors for precipitation of symptoms cold is important. The color changes are first observed after exposure to cold Emotional and nervous upsets, commonly bring on Raynaud's phenomenon, although not so commonly as cold.

The varying degrees of color changes in Raynaud's disease are related to transient changes in blood flow to the digits and are confined largely to the digital arterioles. The changes in the digital arterioles may result from either local faults or central vasomotor factors Local faults in the digital arterioles seem to be responsible when Raynaud's phenomenon is produced only by exposure to cold Central vasomotor faults seem to be responsible when the phenomenon occurs only after emotional upsets or nervous tension.

SYMPTOMS. The first symptom of Raynaud's disease comprises color changes of the skin over the tips of the fingers and occasionally over the toes on exposure to cold These color changes usually begin slowly, often being present in some degree for a period of years, but they may be called to the patient's attention by an acute episode of pallor in one or two fingers on exposure to cold As the disease advances, more fingers are affected, and the extent of the disease in each finger increases until the whole digit is involved, finally the backs of the hands may become affected. The color changes progress successively through pallor, cyanosis and rubor. Pallor is present while the finger is cold Cyanosis may be present with pallor, giving the lifeless hue so characteristic of the disease. Rubor comes on warming the hands. Pain is not a prominent symptom during the attack or in the interval between attacks.

Paresthesia, consisting of numbness, tingling, burning, a feeling of tightness, and a sensation of pins and needles or sticking in the fingers, may occur during the attack In some cases a slight swelling of the involved fingers may occur and even persist during the interval between the attacks.

In the advanced stages of Raynaud's disease the patient may become disabled from the attacks, which occur at any time on exposure to a cool environment or from any emotional stress After the disease has progressed thus far, the attacks may be as frequent and severe in warm weather as in cold weather

Extensive gangrene does not occur in Raynaud's disease, although gangrenous ulcerations may arise on the tips of the digits and cause considerable pain and discomfort In an occasional instance these lesions may become infected and require amputation of the distal parts of the involved finger or fingers

EXAMINATION In the interim between attacks in the mild forms of the disease no abnormalities will be observed on examination. To confirm the diagnosis, it may be necessary to induce the phenomenon by immersion of the extremity in cold water or by its exposure to cold air The extent, nature and duration of the color changes indicate the severity of the disease

Tests for postural color changes are conducted for detection of possible occlusive arterial disease Each peripheral artery is palpated, and if questionable pulsations are detected in an artery, help in making the decision may be gained by occlusion of the other artery or arteries to the region while palpation is continued in the questionable artery

When Raynaud's phenomenon occurs in an arm and is more marked *on one side* than on the other, a scalenus anticus syndrome is suspected as well as a cervical rib

ography. These methods may be used for the detection of arteriovenous fistulas occurring in any accessible regions of the body.

It is usually impossible to correct congenital arteriovenous fistula by surgical means.

Acquired Arteriovenous Fistula. Acquired arteriovenous fistula of the extremities almost invariably is caused by penetrating wounds. These communications may occur in any part of an extremity. The passage of the arterial blood directly to the venous blood indicates an arteriovenous fistula irrespective of how devious the means of communication may be.

SYMPTOMS. Trauma which causes an arteriovenous fistula is followed by profuse and easily controlled hemorrhage.

After trauma the occurrence of varicose veins, edema, stasis pigmentation, ulceration and chronic indurative cellulitis round the spot where the fistula is situated indicates that the stab wound has not healed in the usual manner. Ulceration and stasis ulcer in acquired arteriovenous fistula are characterized by cutaneous changes and other changes in the entire portion of the extremity distal to the fistula as contrasted with venous insufficiency from other causes in which the ulcerations are limited to the surfaces over the malleoli.

Gangrene of distal portions of the extremity may occur as the result produced by shunting the arterial blood away from the capillary bed in the affected parts.

If an arteriovenous fistula is acquired before the epiphyses close, there is an increased length of the affected extremity

EXAMINATION On examination a thrill and a bruit continuous throughout the cardiac cycle can be felt and heard They are accentuated during systole and are diminished during diastole

The temperature of the skin of the extremity affected is increased distal to the fistula This warmth of the skin is characteristic of arteriovenous fistula

A few patients who have traumatic arteriovenous fistula are found to have enlargement of the heart A small fistula causes little, if any, increase in the size of the heart; a fistula of moderate size produces moderate cardiac dilatation, a large fistula invariably produces marked cardiac dilatation and often congestive failure. When enlargement of the heart occurs in cases of arteriovenous fistula, the changes which seem directly responsible are (1) a great increase in cardiac filling owing to acceleration of the velocity of blood and (2) an increase of effective venous pressure of the involved vein and anatomically associated tributary veins proximal to the fistulous connection. The volume of the returning venous blood is increased because of enlargement of the artery and vein in the fistulous circuit

An increased amount of oxygen in the venous blood proximal to the fistula is indicative of arteriovenous fistula. When the fistula is closed by digital pressure, bradycardia (Branham's sign) is often present The systolic and diastolic blood pressures may increase simultaneously with the slowing of the heart rate Since the artery empties directly into the vein, the pressure within the vein approaches that within the artery. The veins may actually pulsate

The cardiac output may be increased or even doubled in the presence of a fistula of moderate size. The increased cardiac size is primarily an adjustment dilatation, and cardiac hypertrophy is responsible for only a small degree of the increase in the size of the heart.

It has been observed by Porter and Baker that an extreme degree of cardiac dilatation can exist over a long period without cardiac failure. If the fistula is large, congestive cardiac failure and death may ensue if the fistula is not repaired

DIAGNOSIS. The presence of a machinery-like thrill and bruit which are accentuated during systole and diminished during diastole is sufficient evidence to enable one to make the diagnosis of traumatic arteriovenous fistula.

The fistula should be closed surgically.

of acute onset result from an arterial occlusion or an acute, severe arteriospasm which is a temporary occlusion of a segment of an artery.

When there is a more gradual onset after injury or operation, the vasospastic changes begin weeks or even months after injury or operation. In the presence of chronic irritation and infection plus the disturbed circulation, bone injury follows. In these cases, however, the osteoporosis may be largely due to inactivity or failure of normal stimulation and of use of the bone.

The symptoms of posttraumatic Raynaud's phenomenon are tenderness, edema and pain, and cold, moist, slightly cyanotic skin with or without roentgenologic evidence of osteoporosis in the region of, or distal to, the injury. The diagnosis is based on the history of trauma or operation preceding the appearance of symptoms.

NEUROGENIC RAYNAUD'S PHENOMENON. The disturbances of the central nervous system which are commonly enumerated as being associated with functional disturbances of circulation are hemiplegia, monoplegia, chronic anterior poliomyelitis, peripheral neuritis, progressive muscular atrophy, myelodysplasia, syringomyelia, causalgia, spina bifida and cord tumors The vascular manifestations consist of persistent pallor and coldness with or without other color changes.

Usually the distinction between functional vascular disturbances secondary to neurogenic disorder and manifestations of organic vascular disease is not difficult. There are coldness and often color changes which are out of all proportion to the objective evidence of occlusive arterial disease.

INTOXICATION In ergot poisoning both vascular and nervous symptoms are observed The vascular manifestation is gangrene, that of poisoning of the central nervous system may be convulsions In some cases, however, both neurologic and vascular symptoms occur which produce a feeling of intense heat and cold, burning pains (St Anthony's fire) and coldness and cyanosis of the extremities. In the severe forms the cyanosis is replaced by gangrene which may appear suddenly. The neurologic symptoms consist of severe psychic disturbances, paresthesia, muscular spasms and convulsions, and in some cases residual anesthesia of the skin and even permanent contraction of the muscles and paralysis of the extremities may be present The neurologic manifestations are more likely to occur in persons who are malnourished than in those who are well nourished

Cases of Raynaud's phenomenon and severe vasospastic disturbance leading to gangrene from the ingestion of ergot preparations for medicinal purposes have been recorded However, large doses of ergot preparations are usually tolerated without any untoward vascular manifestations

Scleroderma. The terms acroscleroderma, acrosclerosis and diffuse scleroderma have been used as synonyms of scleroderma Allen, Barker and Hines accept the term acroscleroderma with Raynaud's phenomenon as designating a scleroderma of the extremities, face and thorax which develops as a late manifestation of Raynaud's disease They restrict the meaning of the term sclerodactylia to a scleroderma which is limited to the fingers Acroscleroderma, used alone, implies a sclerodermic involvement of the skin of the face, thorax and extremities without reference to Raynaud's phenomenon (see page 1357)

Livedo Reticularis. Livedo reticularis (also called livedo racemosa, livedo annularis and asphyxia reticularis) is similar in many respects to other vasospastic disorders The etiology is unknown

Since the condition is of a vasospastic nature, it causes narrowing of the arterioles with an accompanying dilatation of the capillaries and venules The complaint is a persistent bluish to bluish red mottling of the skin of the legs and feet which occasionally extends to the thighs In some instances the hands and arms and the lower part of the trunk are affected The livedo never entirely disappears spontaneously. It is more noticeable on exposure to cold than under other circumstances.

Some patients have coldness, numbness, dull aching and paresthesia of the feet and legs. A few have chronic ulcerations of the skin of the legs. Occlusion of the

or pressure from the scalenus anticus muscle. Sclerodermatous changes may be associated with Raynaud's disease, or the disease may be secondary to generalized scleroderma.

DIAGNOSIS In the majority of instances Raynaud's disease can be diagnosed if there can be elicited a history of episodes of bilateral Raynaud's phenomenon precipitated by cold or emotion On examination there is an absence of primary disease, such as occlusive arterial disease, cervical rib or organic disease of the nervous system which could cause the phenomenon.

When Raynaud's phenomenon has been restricted to one finger or to one extremity for a long time, some secondary causative factor should be suspected When Raynaud's phenomenon occurs in a man, it should be suspected as being due to thromboangiitis obliterans or to some other factor until conclusively proved to be otherwise. If on examination gangrene which results from Raynaud's disease is present, it will be limited to the skin. Sclerodermatous changes and ulceration may complicate Raynaud's disease, but these are strictly limited to the skin and no involvement of any visceral organs will be found

Patients who have Raynaud's disease are treated medically or surgically. In selecting patients for surgical treatment, only those who have trophic changes and scleroderma should be considered Surgical intervention may decrease their disability in cold weather

Secondary Raynaud's Phenomenon. The term secondary Raynaud's phenomenon is employed to designate local changes in the peripheral circulation which permit of changes in color of the skin resembling those of the primary disease. Allen, Barker and Hines have classified the conditions or diseases in which secondary Raynaud's phenomenon may be observed as follows: (1) after trauma: related to occupation and following injury or surgical operation, (2) neurogenic lesions: cervical rib and scalenus anticus syndrome and diseases of nervous system; (3) occlusive arterial disease arteriosclerosis obliterans, thromboangiitis obliterans and embolism; (4) intoxication, for instance from heavy metals and ergot; (5) miscellaneous diseases such as scleroderma, lupus erythematosus and paroxysmal hemoglobinuria.

POSTTRAUMATIC RAYNAUD'S PHENOMENON. Two types of posttraumatic Raynaud's phenomenon may be observed (1) occupational Raynaud's phenomenon and (2) persistent vasospasm or Raynaud's phenomenon following injury or surgical operation

Occupational Raynaud's Phenomenon This is well illustrated by pneumatic hammer disease The rapid oscillations of the pneumatic hammer seem to sensitize the digital vessels of some workmen so that Raynaud's phenomenon occurs readily on exposure to cold There is a wide range of susceptibility to this injury Some workmen are not injured, even after very long periods of using the air hammer

The episodes of Raynaud's phenomenon usually appear first in right-handed men in the third, fourth and fifth fingers The phenomenon does not occur during work unless the tool is cold when in use In susceptible persons the attacks begin within two months to a year after the worker has started to use the hammer. The course of this condition is benign Often workmen are not greatly concerned about the vasospastic phenomena, but accept them as being a part of their occupation

Raynaud's phenomenon may be present in pianists and typists. The vasospastic discomforts involve only one or two digits Once the phenomenon is present, it will continue to be precipitated by exposure to cold even if there has been a change in the occupation.

Following Injury or Surgical Procedure Raynaud's phenomenon may come suddenly, soon after trauma or operation, or may be delayed for weeks or months The phenomenon may be associated with an osteoporosis (Sudeck's atrophy). Instances

SYMPTOMS. The symptoms of obstruction of the superior vena cava are often a throbbing sensation, headache, vertigo and sometimes mental confusion These symptoms are exaggerated by stooping, bending forward or physical exertion. They are likewise increased in the recumbent position, relief is often obtained while the patient is in the sitting or in the half-reclining position. A rapidly developing obstructive lesion produces congestion and an intense edema of the face, shoulders and arms.

EXAMINATION. Cyanosis of the face and upper extremities, and prominence, engorgement and dilatation of the veins of the head, neck, arms and upper part of the thorax are often present

The site of obstruction in the intrathoracic veins and the veins of the upper extremities and head can be determined accurately by determining the limitations of the evidence of increased venous pressure, edema and congestion If the veins of the neck and both arms are involved, the obstruction is situated in the superior vena cava. If a prominent plexus of large veins is seen over the sternum connecting with branches of the internal mammary vein, the obstruction is probably above the level of the azygos vein If the entire superior vena caval system is obstructed, large collateral veins are noted crossing the costal margin, and the blood flows downward over the anterior abdominal wall.

The direction of flow of blood in a dilated superficial vein is determined by stripping out the blood of a vein and compressing both ends of a segment thus freed of blood with the fingers, repeat this procedure and each time remove alternately the two fingers. When the finger in the direction of the blood flow is removed, the vein fills slowly if at all, whereas when the finger opposing the flow is removed, the vein fills rapidly

DIAGNOSIS. Roentgenographic examination, bronchoscopic examination and, if there are enlarged cervical lymph nodes, biopsy of the lymph nodes in the neck or axilla are each of diagnostic value The tumors which produce obstruction of the superior vena cava are nearly always malignant.

Obstruction of the Inferior Vena Cava. Obstruction of the inferior vena cava usually results from thrombosis or thrombophlebitis However, neoplasms, aneurysms, ascites and constriction as the result of adhesive bands and scar tissue from old inflammatory processes and accidental surgical ligation cause inferior caval obstruction

Pain may be present and severe soon after the obstruction It soon subsides. There are bilateral enlargement of the lower extremities with edema, extensive prominence of the superficial veins of the legs, and the presence of dilated and often tortuous superficial veins on the abdomen which extend well up to the thorax. The direction of blood flow in these collateral veins is upward

Edema of the lumbosacral region is frequent Bilateral obstruction of the common iliac veins without obstruction of the inferior vena cava can produce similar findings The occlusion of the inferior vena cava may extend above the level of the renal veins and thus may be incompatible with life. Instances of ligation of the inferior vena cava have occurred without an ensuing edema of the legs or dilated veins

Nonobstructive Diseases of Veins. ***Phlebosclerosis.*** Degenerative lesions of the veins are exceedingly rare. Occasionally there occurs calcification of the medial coat. However, the so-called calcified lesions of the veins which are seen in roentgenograms of the extremities and of the pelvis are calcified thrombi (phleboliths)

Phlebosclerosis, or venofibrosis according to Allen, Barker and Hines, occurs between the ages of 18 and 45 years. The etiology of the condition has been ascribed to gout, lead poisoning and syphilis, and perhaps in some way it may be associated with peptic ulcer

arteries of the toes and gangrene have developed in a few who have this disease.

On inspection of the extremities the reticular, blotchy nature of the color changes is characteristic. The diagnosis can be readily made from the appearance of the extremities. Rarely does this disease cause any serious consequences, though once established it is always present. The disease is common in women who have fat legs

Acrocyanosis. Acrocyanosis seems to represent a generally unstable vasomotor system Lewis and Landis concluded that the fault is local. The disease is often a familial one which is suggestive of morbid heredity. The cause of the disease is unknown.

The disease affects women. They complain of constant coldness and bluish discoloration of the fingers and hands which is worse during the winter than at other seasons.

Examination of the peripheral arteries will not reveal any evidence of occlusive arterial disease. The color changes of acrocyanosis are persistent as contrasted with the intermittent nature of the color changes in Raynaud's disease. There is no history of episodes of blanching, and no scleroderma or development of trophic changes, ulceration and gangrene

DISEASES OF THE VEINS AND LOCOMOTION

Veins of the Leg and Foot The veins of the lower extremity are divided into superficial and deep. The deep veins all have valves and there are frequent communications with the superficial veins.

On the dorsum of the foot is a venous arch which unites with the medial dorsal digital vein to form the commencement of the long saphenous vein

The external or short saphenous vein begins behind the external malleolus, ascends alongside the Achilles tendon, thence over the gastrocnemius to empty into the popliteal vein. Its branches anastomose with those of the long saphenous on the inner side of the leg, and it communicates through the deep fascia with the deep veins It is accompanied by the external saphenous nerve

Obstructive Diseases of Veins. Venous obstruction arises from extrinsic and intrinsic causes. The possible extrinsic causes are numerous; the commonest is a partial obstruction of the *iliac veins* by a gravid uterus during the last months of pregnancy. Varying degrees of venous insufficiency of the limbs as well as permanent damage to the veins of the lower extremities and their valves may result from gestation

Another common cause of venous obstruction of the iliac veins is pressure from pelvic and abdominal neoplasms. Neoplastic obstruction (lymphoblastomas and metastatic carcinomas) is a common cause of obstruction of the iliac veins and also of the superior and the inferior vena cava

The intrinsic cause of obstructive disease of the veins is mainly thrombophlebitis which will be considered later

SYMPTOMS. The signs and symptoms of extrinsic obstruction of the iliac veins as well as the veins distal to them are enlargement of the extremity or extremities distal to the obstruction, with or without edema, congestion of the skin, prominence of the superficial veins, sometimes dilatation to the point of formation of a varix, and increase of venous pressure. Pain is not severe. Some pain from a congestive distention in muscles of the extremity or extremities may occur on dependency. This discomfort is relieved by elevation of the affected member.

EXAMINATION. In many instances the cause of the obstruction of the iliac veins is easily determined by examination by physical means of the pelvis and the rectum

Obstruction of the Superior Vena Cava. Obstruction of the superior vena cava is a rare condition The causes of obstruction of this vessel are mediastinal tumors, chronic mediastinitis, thrombophlebitis, constrictive pericarditis and congestive heart failure.

Pain, swelling and tenderness vary with the severity of the inflammation and the degree of congestion distal to the site of obstruction Fever, tachycardia and malaise are variable among patients who apparently have the same degree of local involvement. Thrombi in superficial veins are palpable.

Thrombophlebitis of the saphenous systems is often secondary to infectious disease, cachectic states, or blood dyscrasias The multiple lesions appear as red, painful, tender, raised linear ridges in the skin In small superficial veins the lesions may be palpated as firm, cordlike segments in the course of a visible vein. The inflammatory reaction undergoes involution in from 7 to 18 days but the thrombosed portion of the vein can be felt for a much longer period In some instances, in the presence of arterial insufficiency, necrosis of the skin occurs over the lesion (necrotizing phlebitis).

The muscular veins and deep veins of the calf are commonly affected by postoperative thrombophlebitis. When this occurs, there are pain in the calf and tenderness in the calf muscles Dorsiflexion of the foot will occasionally cause pain in the calf in some early and otherwise subclinical thrombosis of the muscular or deep vein of the calf (Homans' sign) The presence of pain and tenderness in the calf during the immediate postoperative period may denote a thrombophlebitis of the short saphenous, muscular or deep tibial veins

Thrombophlebitis of the popliteal and the femoral veins causes pain and some transient swelling and congestion of the lower part of the leg and the foot There may or may not be fever Iliofemoral thrombophlebitis is characterized by a fairly sudden onset of fever and pain present along the course of the affected vein and thence passing distalward to the foot The pain may begin in the gluteal region or in the calf The superficial veins are somewhat prominent and distended, and the skin may be diffusely or locally cyanotic There is enlargement of the entire extremity.

Pain and often local swelling and redness at the site of the thrombosis followed by enlargement of the extremity and often fever are *diagnostic* of thrombophlebitis A superficial thrombophlebitis involving small veins is distinguishable by the linear rather than circular shape of the lesions, their smaller size, lack of ulceration and comparatively rapid involution Deep thrombophlebitis of the calf may resemble myositis, fibrositis and sciatic pain except that there is prominence of superficial veins

COMPLICATIONS AND SEQUELAE Chronic venous insufficiency of the limb is a serious complication of iliofemoral thrombophlebitis and saphenous thrombophlebitis

Phlebothrombosis (*Secondary Thrombophlebitis, Marantic Thrombophlebitis*). In phlebothrombosis there is no evidence of antecedent disease or injury of the vein Thrombosis is first The phlebitis develops as a reaction to the thrombosis

[illegible]

infectious trauma to pelvic veins may form a locus for the development of an extending thrombus in some cases However, after delivery multiple thrombi occur in small veins and venules of the uterus, there are changes which occur abruptly in the large dilated veins in the region of the broad ligaments, there is the loss of blood during delivery, and there are subsequent changes in the constituents of the blood itself.

Embolism, usually in the lungs, is the most serious complication of postoperative venous thrombosis It is the result of phlebothrombosis and occurs in many cases in which there is no clinical evidence of thrombophlebitis. Therefore it is assumed that thrombosis has occurred in some one of the peripheral veins and that either the entire thrombus became the embolus, or the part of it which remained at the original site failed to produce local symptoms.

The veins are small. A loss of endothelium and a hyalinization of the denuded surface are followed by subintimal fibrosis

Venofibrosis rarely produces clinical symptoms.

On palpation there is the sensation of hard cords which are small, mobile and smooth. Frequently a longitudinal groove in the skin corresponds to the location of the involved vein. The diagnosis is made on the forementioned findings.

Rupture. A vein rarely ruptures spontaneously unless diseased. Rupture is usually caused by trauma The rupture of a vein is rarely of serious importance so long as the skin is intact. The hemorrhage from a ruptured vein is limited by the tissue pressure and the formation of a hematoma.

Thrombophlebitis, Phlebothrombosis and Pulmonary Embolism. Thrombophlebitis is phlebitis in which a thrombus is present. By some it is defined as partial or complete venous occlusion by an intravascular thrombus which is associated with inflammation of the wall of the vein and has a firm mural attachment Phlebothrombosis is an occlusion of a vein by an intravascular thrombus which is not associated with inflammation of the wall of the vessel, is loosely attached to the wall and so can be easily detached, resulting in pulmonary embolism.

Thrombophlebitis. Thrombophlebitis occurs (1) as a local thrombophlebitis, (2) as suppurative thrombophlebitis, (3) as spontaneous thrombophlebitis, (4) as ischemic thrombophlebitis, and (5) as nonrecurring idiopathic thrombophlebitis

In *local thrombophlebitis* there is direct injury or a pre-existing disease of the wall of the vein The common example of this condition is the thrombophlebitis produced as a result of an injection of a sclerosing solution

Thrombophlebitis may originate at the site of contusions, lacerations and fractures even though there is no evidence of infection of the tissues.

A large number of lesions, usually of the smaller veins or venules, which occur as a part of inflammatory but nonsuppurative lesions are classed as thrombophlebitis of inflammatory or toxic origin These thrombi may be minimal or moderate in extent but are rarely extensive Examples of these lesions are the venous occlusions which occur in association with erythema nodosum, tuberculosis, gummas and granulomas

Suppurative thrombophlebitis may occur as the result of involvement of the wall of the vein by a severe suppurative disease. In these cases the thrombus itself is highly infected

Spontaneous thrombophlebitis may occur in varicose veins A history of minor injuries to a varix or constriction by a tight bandage or garter may be elicited In some cases thrombophlebitis may develop in varicose veins after operations, childbirth or infectious disease.

In extremities in which there is arterial occlusion with the consequent *ischemia* an extensive *secondary thrombosis* of the veins is often observed The venous occlusion is usually of little importance in comparison with the arterial disease.

Thrombophlebitis may develop primarily without any known injury to the vein in cases in which operation has not been performed, delivery has not occurred, and there has been no evidence of infectious disease, noninfectious systemic disease, or blood dyscrasia.

Patients who have gout or those who have gouty inheritance may have thrombophlebitis migrans, in which the lesions are usually bilateral and appear to migrate or jump from one vein to another.

Idiopathic thrombophlebitis of the nonrecurring type often involves a large vein in a lower extremity of a patient otherwise healthy It has the same clinical features as secondary or complicating thrombophlebitis No significant predisposing factors with regard to age or sex are known (Allen, Barker and Hines).

In all types of thrombophlebitis there is objective evidence of thrombosis and inflammatory reaction in the various coats of the venous wall at the site of the formation of the thrombus. The red or coagulation thrombus, the white or agglutination thrombus, and the mixed thrombus are described The commonest type of thrombus is the mixed type

the internal malleolus, or occasionally on the feet or toes if the patient has gone barefooted. These ulcers often become chronically infected and odorous.

Perthes' test for occlusion of the deep veins of the legs is based on the physiologic actions of the skeletal muscles in the leg which influence the venous circulation toward the heart. During contraction of the muscles in the leg in walking there is a compression to the deep veins, resulting in a constriction and forcing the blood to pass upward toward the heart During muscular relaxation the empty and collapsed deep veins fill again with blood aspirated from the superficial veins. This is known as the diastolic phase or muscular diastole.

The Perthes test consists in placing a tourniquet around the thigh just above the knee, constricting the superficial long saphenous vein sufficiently to prevent the reflux of venous blood, and having the patient walk vigorously or flex and extend the knee repeatedly. The interpretation of this test is as follows:

1. *If the varicosities in the leg collapse during muscular contraction, the deep vein* is patent, permitting the blood to pass into the deep circulation through the deep communicating veins and up toward the heart. This is known as a Perthes negative and permits treatment to the varicosities.

2. If the varicosities do not collapse but become more distended and the patient feels pain or severe cramps in the leg during muscular contraction, the blood cannot pass through the deep circulation and up to the heart because there is an occlusion or thrombosis in the deep vein—positive reaction.

In the presence of certain segmental thromboses or segmental occlusions in the deep vein in the thigh the usual Perthes reaction may be erroneously negative. Barone has suggested carrying out Perthes' test at different levels of the leg to prevent such an error.

The modified test (Barone) is carried out as follows The tourniquet is placed first below the knee above the varicosities and the patient is instructed to walk as in the Perthes test If the veins below the tourniquet collapse, one repeats the test by placing the tourniquet 5 inches (about 13 cm) higher If the veins likewise collapse, one repeats the test again and again, each time placing the tourniquet at levels 5 inches higher up to the groin The interpretation is as follows (1) If the varicosities below the tourniquet collapse every time the patient walks with the tourniquet at different levels, for example

of an existing thrombus in the deep vein.

Diagnosis Chronic venous insufficiency is diagnosed (1) by edema of the legs which disappears after recumbency, (2) by dilatation and prominence of superficial veins, and (3) by a tendency to aching distress in the limb when the patient is in the erect posture, relieved by recumbency in a comparatively short time, particularly if the limb is elevated.

The leg ulcers are differentiated from syphilitic ulcers, which occur in the upper portion and often on the lateral aspects of the leg These ulcers are usually without the chronic induration and skin color changes of the varicose ulcer.

DISEASES OF THE LYMPH VESSELS AND LOCOMOTION

Lymphedema. Lymphedema is the manifestation of an obstruction to the central flow of lymph and the inability of the newly formed collateral channels to develop adequate valves As a result of stagnation of the lymph its protein content is increased, fibroblasts proliferate and the resultant fibrosis increases the stasis Thus as the stasis of lymph increases, the tissues are less viable and often inflammation is present, and then more stasis ensues

There are acute and chronic lymphedemas. The acute lymphedemas are commonly present during the course of acute infections

Chronic Lymphedema. Homans classified the chronic lymphedemas as primary and secondary.

Varicose Veins (Phlebectasia, Venous Aneurysm). Some varicose veins develop spontaneously, while others develop distal to a venous obstruction.

Varicose veins which develop spontaneously are the result of a hereditary weakness in the structure of the vein and its valves. The veins are constitutionally poor and are unable to withstand the normal amount of stress and strain resulting from increased abdominal pressure and abdominal obesity, or the opposite, emaciation, both of which are common as age increases. Atrophic lesions of the skin, such as diffuse idiopathic atrophy or acrodermatitis chronica atrophicans and extensive scars, occur

Varicose veins which develop distal to a venous obstruction are a late complication of obstruction of the vena cava.

Varicose veins affect both men and women

The essential demonstrable pathologic changes in varicose veins are (1) dilatation, (2) elongation and tortuosity, (3) loss of elasticity, (4) variations in the thickness of the wall and (5) disappearance of the valves of the veins.

SYMPTOMS. Often extensive varicose veins of the legs may not produce any subjective symptoms. When symptoms are present, they consist of an increased tendency to fatigue of the leg muscles, a sensation of fullness and congestion, and soreness in the region of the veins.

Superficially in the skin there may be an eczematoid dermatitis, pigmentation, paresthesias of burning, pain and itching in the region of varicose veins.

EXAMINATION Have the patient stand in good light with bare legs In most instances varicose veins are apparent on inspection In obese persons some varices, particularly of the long saphenous vein and of other veins, can be detected and examined more easily by palpation, particularly with regard to their size and tortuosity.

The deep veins are almost always competent unless the patient has had iliofemoral thrombophlebitis previously. Iliofemoral thrombophlebitis frequently leaves the iliofemoral vein partially obstructed or with incompetent valves However, in these cases compression of the superficial veins by an elastic bandage is usually well tolerated by the patient.

Chronic Venous Insufficiency. Chronic venous insufficiency sometimes is called venous stasis, stasis edema, stasis eczema, stasis ulcer, varicose ulcer, or postphlebitic ulcer. The basic cause for chronic venous insufficiency is the destruction and deformity of the small venules and capillaries to the extent that insufficient numbers are left intact to carry on without abnormal congestion

SYMPTOMS The first and often the only symptom of chronic venous insufficiency is subcutaneous edema which occurs after standing and walking The edema is above the shoe tops It will develop in the feet if the patient wears loose shoes or slippers or no shoes or slippers at all The discomfort in chronic venous insufficiency is not great. A dull ache sometimes follows prolonged standing, but will go within five to thirty minutes when the leg is elevated If a patient who has osteoarthritis of the knees has venous insufficiency, the joint changes are often more severe. In the presence of ulcers and indurative cellulitis the pain is more intense.

EXAMINATION. There may or may not be cyanosis of the skin. The skin over the edematous regions may be irregularly covered by areas of brown pigmentation (hemosiderin) Associated with the pigmentation often there is dermatitis or eczema. The eczema frequently is of a chronic scaling variety accompanied by minimal subjective manifestations. It may be limited to the medial aspect over the lower third of the tibia. A more diffuse eczema may be present.

A hard, brawny induration of the skin and subcutaneous tissues may be present If the skin is depressed over the entire circumference of the ankle and lower part of the leg, or just in spots, an indurated cellulitis is present. Ulceration may be present and if so, this is one of the common and disabling manifestations of chronic venous insufficiency. These ulcerations appear just below the malleoli, especially

Advanced lymphedema offers no diagnostic difficulties. The brawny, indurated skin and hypertrophied limb of advanced lymphedema bear little resemblance to manifestations of edema in other diseases It is only when lymphedema is not associated with changes in the appearance and texture of the skin secondary to inflammation that difficulty arises.

TUMORS OF BLOOD AND LYMPH VESSELS

Benign Tumors of the Blood Vessels. ***Telangiectasia.*** The commonest cause of telangiectasia is exposure of the skin, particularly of the face, to wind and sun A less common but well-known cause is excessive exposure of any part of the body to radium or roentgen rays. Telangiectasia is often associated with acne rosacea, xeroderma pigmentosum, lupus erythematosus, morphea and syphilis.

Four types of localized telangiectasia are described, namely, spider nevus, senile ectasia, hereditary hemorrhagic telangiectasia and pulsating telangiectasia.

A *spider nevus* (nevus araneus) appears as a raised red dot from which fine vessels radiate. The lesions occur on the face, neck, thorax, backs of the hands or other parts of the body. These nevi develop spontaneously during adult life and in those who have delicate skins However, they are of little clinical importance and treatment is not necessary

Senile ectasia, senile vascular nevus, appears as multiple small papillary lesions of a bright red or purplish color This vascular nevus does not imply the presence of any known visceral disease

Hereditary and familial hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome) is characterized by the development of multiple telangiectatic lesions of the skin and mucous membranes The lesions occurring in the mucous membrane of the nose have a definite tendency to hemorrhage and cause frequent and often serious epistaxis by such minor trauma as sneezing, coughing, vomiting, or strain while lifting a heavy weight The presence of these lesions on the mucosa of the oral cavity, lips, tongue, pharynx or on the skin of the face and fingers may be the focus of excessive bleeding

[illegible] from the history of bleeding from a region where telangiectasia [illegible] originating from [illegible] The lesions may [illegible] tendency to blanch on pressure from a glass slide.

Pulsating telangiectasia (*pulsating hemangioma*) occurs on the face, hands and thorax of adults The lesions are larger (2 to 5 mm in diameter) and more raised than the lesions of hereditary hemorrhagic telangiectasia

The radiating, pulsating telangiectatic vessels are larger than those of spider nevi. The pulsations, if not obvious, can be demonstrated by making light pressure by means of a glass slide over the lesion

Pulsating telangiectasia occurs in association with hepatic disease, pregnancy and lymphosarcoma Severe hepatic disease was present in all of the cases reported by Williams and Snell These authors stated that telangiectasia preceded the development of the clinical signs and symptoms of hepatic disease. This does not mean, however, that all those who have severe hepatic disease have pulsating telangiectasia or that pulsating telangiectasia is always indicative of hepatic disease

Hemangioma. A hemangioma is a slowly growing, benign tumor composed of newly formed blood vessels. Hemangiomas are of congenital origin and are commoner in women than in men Occasionally the tumors increase in size with the onset of menses or during pregnancy

Hemangiomas are variously classified as nevus flammeus, capillary, cavernous, diffuse, racemose, cirsoid and congenital arteriovenous fistulas Several of these different kinds of hemangiomas may occur in the same individual

The *primary* lymphedemas comprise the hereditary or familial, the congenital, the praecox and, finally, the simple forms. The primary lymphedemas are noninflammatory and are somewhat commoner than the secondary noninflammatory lymphedemas.

PRIMARY LYMPHEDEMA (Lymphedema Praecox). The onset in the majority of cases is in adolescent girls. *There is an accentuation during menstruation* It has been postulated that the additional load thrown on the lymph vessels by rapidly developing reproductive structures induces functional incompetence or allows entrance of infection into the lymph trunks and nodes in the pelvis

Spontaneously and without any known cause the patient notices a puffiness about the foot or ankle, where in most instances it stops However, edema may progress up the leg, and often the entire limb may be involved within a few days or weeks. As *the condition develops, a smooth skin becomes roughened, the soft edema* becomes resistant to pressure, tissue hypertrophy occurs and the leg becomes permanently enlarged, unsightly, ungainly, uncomfortable, and disliked by the patient. A dull, heavy sensation is present Ulceration of the skin does not occur

HEREDITARY CONGENITAL LYMPHEDEMA (Milroy's Disease). This condition affects a sufficient number of blood relatives to indicate that a disturbance in the genes is responsible Its manifestations are the same as those of lymphedema praecox.

The pathologic changes in congenital lymphedema are characterized by thickening and canalization of the subcutaneous tissue and the adipose tissue. However, in this form of lymphedema there is neither thrombosis of lymph vessels or blood vessels nor evidence of inflammation. In other forms the foregoing changes are repeated, and in addition there is atrophy of muscle, nerve fibers and sweat glands, and evidence of infection by leukocytic infiltration.

The characteristics of congenital lymphedema are the presence at birth of a diffuse *swelling involving part or all of a single extremity; the disproportionate* increase in the size of the involved extremity as contrasted with the uninvolved companion member, the absence of pain, ulcers and recurrent attacks of infection, and the otherwise good health of the person affected.

The presence of a firm swellin [illegible] definitely reduced in size when the extremity is eleva [illegible] the enlargement is nodular rather [illegible] a single part. Congenital arteriovenous fistulas increase the length and the girth of the extremity The temperature of the skin is higher than that of the companion member. The superficial veins are dilated, and the oxygen content of the blood from superficial veins in the affected regions resembles that of arterial blood Congenital hypertrophy or congenital hemihypertrophy of an extremity is *rare and this condi*tion is rarely limited to a single member

SECONDARY LYMPHEDEMAS. Secondary noninflammatory lymphedema includes instances of occlusion of the lymphatics as the result of malignant tumors, surgical removal of lymph nodes, pressure, and irradiation therapy. Whether lymphedema that ensues on irradiation therapy is brought about by fibrosis caused by irradiation or by metastasis of the malignant disease for which irradiation is given cannot be *determined* with certainty

Inflammatory Lymphedema. Inflammatory lymphedema may be primary or secondary It may be a part or a result of venous insufficiency, trichophytosis, systemic disease or filariasis, or may be due to local tissue injury or inflammation.

All examples of inflammatory lymphedema, *exclusive of the chronic form,* have one feature in common; namely, single or recurrent attacks of acute cellulitis and lymphangitis

Pregnancy and systemic disease such as influenza, typhoid fever, pneumonia, malaria and filariasis may lead to recurrent attacks of cellulitis and *lymphangitis* and result in lymphedema.

anastomosis. This is an end-organ situated in the derma and cutaneous tissue and often beneath the nails. The conglomeration of tissue acts as a control of the peripheral circulation.

The glomus is compared to a thermostat in that anything which disturbs it should cause some disturbance of the heat regulation of the body. When a tumor develops in a glomus, the normal function is disturbed. When the lesion is touched or irritated by heat or, more often, by cold, the circulation of an entire half of the body may be disturbed by the vasomotor activation. A glomus tumor may occur at any age. Trauma is often associated with but probably is not the cause of glomus tumors.

SYMPTOMS. Pain may be present for a long time before the tumor becomes visible. These lesions are usually single although multiple tumors are recorded. Glomus tumors are not malignant.

EXAMINATION A glomus tumor is a small, purplish nodule either in the skin of an extremity or under the nail The tumor rarely exceeds a few millimeters in diameter.

These tumors are so exquisitely painful that touching the lesion usually provokes a paroxysm of severe pain A satisfactory method for examination for a glomus is to ask the patient to indicate with the tip of his finger the site of maximal pain. The adjoining skin is examined with the point of an ordinary steel pin. The normal or surrounding skin or nail, if the lesion is subungual, is not unduly sensitive, but the instant that slight pressure is made over the site of the glomus tumor the patient will withdraw the extremity from the hands of the examiner.

Anteroposterior and lateral roentgenograms of the digit may reveal a small excavation of the phalanx from erosion caused by the tumor.

DIAGNOSIS. The diagnosis is established by histologic examination of the glomus tissue.

The presence of a bluish or purplish lesion in the skin of an extremity, and especially under the nail of a digit which when touched causes the patient acute pain, is sufficient evidence to warrant suspicion of a glomus tumor. The exposure of the lesion to cold will produce neuralgia-like pain which seems to originate in the lesion and may spread to involve the entire extremity, and may produce vasomotor changes

The tumor should be surgically removed

Malignant Tumors of the Blood Vessels. ***Hemangio-Endothelioma.*** Hemangio-endotheliomas are malignant tumors arising from the endothelial cells of the blood vessels Hemangiosarcomas contain both fibroblastic connective tissue and vascular tissues.

Hemangio-endotheliomas occur in any part of the skin and subcutaneous tissue They begin as small tumors of millimeter size and increase to about 4 inches (10 cm) or more in diameter These tumors are dark red, whether situated in the skin or in the mucous membranes They are soft and have a tendency to ulceration and bleeding A hemangio-endothelioma situated in the gastrointestinal tract often causes exsanguinating hemorrhages A differentiation of benign hemangiomas and hemangio-endotheliomas is possible only by histologic study.

One type of hemangio-endothelioma (Ewing's tumor) involves the shaft of long bones, particularly the shaft of the femur Two thirds of Meyerding's patients who had this tumor were boys or men less than 30 years of age. The discomfort suffered by these patients was pain at the site of the lesion The correct diagnosis of these tumors can be made only by biopsy

Hemangio-endotheliomas grow slowly and metastasize slowly but there are many exceptions. When metastasis has occurred, the prognosis is grave.

The treatment of hemangio-endotheliomas without metastasis consists of wide surgical excision

Nevus flammeus (port-wine stain, birthmark) is a form of capillary hemangioma It is a flat well-demarcated purplish red discoloration of the skin which blanches easily on pressure Elevated small nodular tumors may be scattered through the lesion. The lesions vary greatly in size and may be multiple. They are commonest on the face, less common on the trunk or extremities. One of each 3 infants is born with a small nevus flammeus in the occipital region Most of these nevi gradually disappear as the children grow older. Occasionally a nevus of this type is disfiguring and extends over large portions or half of the body. Such an extensive lesion is usually present at birth. It does not extend but enlarges as the part grows. When nevus flammeus occurs on the lower extremities, it may be a part of deep-seated *cavernous hemangiomas or multiple arteriovenous fistulas.*

Capillary hemangiomas (strawberry nevi, capillary nevi) are circumscribed, finely lobulated, elevated, bright red to purple-red tumors which are present on the skin of the face or elsewhere at the time of birth. These tumors occur singly or multiply and vary from a few millimeters to several centimeters in diameter and may attain a thickness of 1 to 2 cm. They blanch incompletely on pressure.

Cavernous hemangiomas (nevi cavernosi, cavernomas) are tumors composed of masses of dilated thin-walled vessels and are the commonest type of true hemangiomas They are present at birth They often continue to enlarge throughout life Cavernous hemangiomas are multiple and occur in all organs of the body. The common situations are the face, neck, oral mucosa, extremities, liver, bones (par*ticularly the vertebrae), stomach and intestine. In a vertebra they have to be dif*ferentiated from Paget's disease and metastatic malignant lesions. On an extremity a cavernous hemangioma often involves skin, subcutaneous tissue and muscle It is a localized but poorly demarcated spongy tumor with multiple bluish, soft nodules resembling dilated veins just under the skin; on elevation of the part the tumor shrinks but usually does not disappear. Varicose veins may be associated

Diffuse hemangiomas (diffuse systemic hemangiomas) when present may involve a large part or all of one or more extremities, one side of the body or a large area over a shoulder and side of the thorax.

The extremity is usually enlarged and irregular. The lesions resemble varicose veins of varying sizes but look queer because they are all over the extremity. The *affected leg feels heavy and aches after walking. The lesions* tend to collapse on elevation Multiple arteriovenous fistulas may coexist but their presence is difficult to prove. Nevus flammeus may be associated.

The presence of phleboliths may be demonstrated by roentgenograms of the extremity.

Cirsoid hemangioma, sometimes designated racemose hemangioma, and known also as cirsoid aneurysm and congenital arteriovenous fistula, is a progressive and bone-eroding, pulsating lesion in the region of the neck which is similar to an extensive congenital arteriovenous fistula Cavernous hemangiomas and port-wine stains may be associated with multiple arteriovenous fistulas

Spontaneous involution often occurs in these angiomas; therefore it is well to wait *for several years before considering treatment. At the* very best, treatment of these conditions by the plastic surgeon is not all that is to be desired

For the treatment of cavernous hemangiomas and the mixed capillary and cavernous types about the face and neck Figi stated that the implantation of two to eight 0 5 millicurie radium seeds is the preferable treatment for young children

Glomangioma or Glomus Tumor. A glomus is a small conglomeration of blood vessels In the body there are various glomera, for instance, glomus caroticum, glomus carotideum, glomus choroideum and glomus coccygeum. Tumors may arise in any of these glomera, but here interest is on the cutaneous glomus, digital glomus or the neuromyo-arterial glomus, which is the total unit making up a Sucquet-Hoyer

axilla, groin, retroperitoneal space, pelvis, thoracic wall or sacral region. The cystic mass is compressible and thin-walled and transilluminates well Cystic hygromas become infected after respiratory infections, surgical operation or radiation, and when such infections occur, they are always serious and may be fatal. If treatment is contemplated, it should be surgical removal.

DISEASES OF THE MUSCLES AND LOCOMOTION

History. In recording the history of a complaint referable to the muscles, attention is paid to the earlier occurrence of conditions that could lead to secondary involvement of the muscles, such as acute infectious disease; for example, acute rheumatic fever, syphilis, trichinosis and diseases of the nervous system.

Direct or indirect trauma to skeletal structures is a common cause of muscular dysfunction The presence of pain and its situation, and whether the pains or the disability appeared immediately after an injury, or only some time later, may be diagnostically helpful.

Examination of Muscles. The general musculature of the patient is inspected In some the muscles have always been small; in others the muscles are voluminous. The volume depends partly on heredity, partly on the daily activity, and, most of all, on the somatic type. The mesomorphs are characteristically heavily muscled individuals

A completely absent muscle, owing to congenital defect, is rarely missed by the patient and thus no complaint is made of its absence Slight atrophy will occur whenever muscles are not used For recognition of this atrophy from disuse, comparative measurements may be required

A large part of the mass of muscles lies so near the surface that individual muscles often can be easily grasped by the palpating hand, others lie deep and are inaccessible On palpation the form of the muscle, its tone, its consistency, and whether or not it is tender on pressure are observed

A relaxed muscle feels soft, a contracted muscle feels firm Normally the consistency of a muscle is even throughout If firmer foci are felt, they are pathologic and are often due to rupture of some muscle fibers, or to abscesses, hernias, scars, gummas or tumors Free fluid or pus within a muscle gives rise to fluctuation on palpation If the testing fingers are applied in a line at right angles to the long axis of the muscle, fluctuation can often be felt in normal muscular tissue. The muscle is correctly palpated by applying the palpating hand parallel to the long axis of the muscle.

In making comparative measurements of the size of muscles in the arms or legs a steel flexible tape is employed and should be applied at exactly the same level on corresponding limbs, thus, in measuring the volume of the thigh, it is well first to draw transverse lines at distances about 4 inches (10 cm) apart above the upper margin of each patella, and then to measure the circumference at each of these levels It is well, also, to make several measurements at each level and to record the arithmetic mean A difference of less than 0.5 cm easily lies within the limits of normal variation and should be disregarded unless the difference is consistent over a considerable portion of the length of the leg or arm.

Enlargement of the muscles of a part or as a whole may be due either to true [illegible] so-called pseudohypertrophy, which

[illegible] pathologic position of the limb to which it is attached, thus a shortened biceps brachii causes flexion of the forearm, and a shortened iliopsoas flexes the hip

It is important, for instance in skin cancer, to determine whether or not the process involves the muscles or the overlying fascia. To determine this, ascertain whether the mass becomes fixed on contraction of the muscle

Hemangiosarcoma. The distinction of hemangio-endotheliomas, hemangiosarcomas and malignant types of spindle cell sarcomas is not always possible.

Hemangiosarcomas are rare tumors which develop at any age and in any part of the body. If near the surface of the body, these tumors are soft, bluish red, and may be surrounded by smaller soft nodules. Thrills are often palpated and multiple-pitched bruits may be auscultated over deeply set tumors The accurate diagnosis of these tumors is made only by biopsy.

The treatment of hemangiosarcomas is unsatisfactory by any means.

Kaposi's Sarcoma (*Multiple Idiopathic Hemorrhagic Sarcoma, Idiopathic Multiple Pigment Sarcoma*). The etiology is unknown. In some instances the lesions have followed trauma or exposure to cold. Approximately 9 of each 10 who have the disease are men The sarcoma is most commonly a disease of elderly people, although it may affect those of any age

Characteristic of this rare disease is a multiplicity of lesions. Hemorrhage occurs into the cutis, and there are deposits of hemosiderin and infiltration into the layers of the cutis. There are proliferations and formation of new and imperfect capillaries with cavernous spaces Metastasis occurs by way of lymph channels

The lesions often appear first on the hands or feet or in the region of the ankles, but they may occur in any part of the body They vary in size from 1 mm. to several centimeters in diameter and are discrete or grouped, bluish red or reddish brown, nodular discolorations. The lesions may extend along superficial veins, and often considerable edema and tenderness develop in the extremities. Localized purpura and thrombosis in superficial veins are common. Old lesions may appear to involute and leave atrophic pigmented scars. Metastasis may occur to almost any organ in the body, particularly the gastrointestinal tract, liver, lungs, and regional retroperitoneal and mesenteric lymph nodes. Some evidence indicates that the so-called metastatic lesions are multiple primary foci. In rare cases the earliest lesions may be in the viscera

The diagnosis is made by biopsy. Kaposi's sarcoma often resembles various types of granuloma, melano-epitheliomas and venous insufficiency with purpura

The prognosis is poor. The patients live from 2 to 10 years or longer Repeated roentgen treatment offers the only hope for prolongation of life

Tumors of the Lymph Vessels. Enlargement of lymphatic vessels (lymphangiectasis) is present but not apparent in all types of lymphedema and chronic lymphatic obstruction. Occasionally a dilated lymph vessel is visible, appearing as a translucent, bluish or slightly pink tubule. On spontaneous rupture or aspiration a clear or slightly yellow fluid is obtained.

Lymphangiomas comprise (1) simple lymphangioma, (2) cavernous lymphangioma, (3) *lymphangioma circumscriptum and* (4) *cystic lymphangioma*

Simple lymphangiomas are situated on skin or mucous membranes and are benign congenital tumors The *cavernous lymphangioma* is present at birth It grows slowly and is the commonest benign tumor of lymph vessels The tumors vary in size and may be [illegible] of dilated lymphatic [illegible] come [illegible] may cause enlargement of these parts, for instance, macroglossia, micro[illegible] or [illegible]omala.

Chylangiomas are cavernous lymphangiomas of the mesentery arising from the lacteals. *Lymphangioma circumscriptum* occurs in eyelids, conjunctivae, orbit, mouth, pharynx, tongue, the upper extremities, axillary or scapular regions, and in the groin or upper part of the thigh. The lesion appears as a crowded deep-seated vesicle Hypertrophy of the skin may occur over older lesions, giving them the appearance of warts, or they may be obscured by telangiectasia

Cystic lymphangiomas (cystic hygromas) are present at birth They are frequently situated in the neck, where they may grow upward toward the parotid gland and ear or downward to the axilla or to the mediastinum They may be present occasionally in the

presence of spina bifida, poliomyelitis, tuberculosis, fractures, neural or peroneal type of muscular atrophy, or muscular dystrophies is required.

Congenital Clubhand. Congenital clubhand, like congenital clubfoot, is due to maldeveloped muscles. It is observed less frequently than clubfoot

Congenital Elevation of the Scapula (Sprengel's Deformity). Abduction at the shoulder is limited since the scapula cannot be rotated. Passive rotation and active rotation of the scapula are diminished or absent because of fibrous or bony attachments between the scapula and the ribs

The affected scapula is elevated, and rotated so that its lower angle is nearer than normal to the spinal column, and the shoulder is advanced. Scoliosis and torticollis may be associated

The diagnosis is based on the forementioned findings. Roentgenograms reveal that the scapula is shortened so that the transverse diameter is relatively increased.

Congenital Contractures of the Extremities. These contractures are designated also amyoplasia congenita, multiple articular rigidity and arthrogryposis multiplex congenita Immobility of one or more joints is present as the result of absence, or incomplete development, of associated muscles

Boys and men are affected more frequently than girls and women The rigidity may affect the muscles of only one joint or the whole limb. It may be bilateral and symmetric. The commonest type of congenital contracture is that in which all four extremities are fixed in extension In some there may be fixation of the knees and the hips in flexion The whole limb commonly is slightly abducted

The affected limbs are often shortened and the range of movement at affected joints is limited to a few degrees because of muscles which are grossly defective or absent Congenital dislocation of the hips and other deformities may coexist. Roentgenograms do not reveal any bony alterations of the joints or capsules, but the muscle shadows may be very small

The diagnosis is based on the objective findings described in the foregoing paragraphs in the presence of negative results of roentgenographic examination of the joints There is little or no spontaneous improvement In severe instances surgical procedures may be helpful

HEREDOFAMILIAL DISEASES OF THE MUSCLES

The Muscular Dystrophies. The term muscular dystrophy designates a disease which is characterized by progressive wasting and paralysis of the skeletal muscles The different types of dystrophies are distinguished by the age at onset, the presence or absence of pseudohypertrophy, and the particular muscles first affected. The following forms are recognizable even if not diagnosable (1) the facioscapulohumeral type of Landouzy-Déjerine, (2) the juvenile scapulohumeral type of Erb, (3) the pseudohypertrophic type of Duchenne and (4) the femoral type of Leyden-Moebius It is abundantly clear that there is no real justification for separate descriptions of these forms

Etiology This disease may be regarded as a heredofamilial degenerative process affecting the muscles Several members of a family or their descendants are affected, or the condition often can be traced through several generations Males and females are affected alike, and either men or women may transmit the disease to their children. It has been concluded that the mode of inheritance varies in different families, and may be of at least three different types simple dominant, simple recessive, and sex-linked recessive

Pathology The muscles may be either enlarged and firm, or small and soft.

No changes have ever been demonstrated in the nervous system other than the mild alterations of the anterior horn cells and motor nerve endings which may be considered secondary In recent years it has been suggested that disturbances in the sympathetic system are to blame for muscular dystrophies, but there is still no satisfactory evidence to support this hypothesis

The tenderness of a muscle to pressure is tested by pressing portions of the muscle between two fingers rather than by pressing the muscle against underlying bone. The tenderness elicited by the latter method may be due to an inflamed periosteum and not to a tender muscle.

Spasm in skeletal muscle seems to be a reversible state of sustained involuntary contraction accompanied with muscular shortening and associated with electrical potential changes. The diagnosis of muscle spasm is often made in various types of low back pain, fractures and poliomyelitis according to Harell, Mead and Mueller who used electromyographic technics and did not find muscle spasm present in these conditions The clinical diagnosis of spasm in peripheral conditions such as backache, fracture or poliomyelitis is erroneous in a large percentage of cases.

Muscle spasm is differentiated from muscle spasticity, which is often caused by lesions of the upper motor neurons of the central nervous system. A true spasm is characterized by sustained muscular contraction. Sustained contraction or spasm is not commonly present in association with spontaneous somatic pain.

CONGENITAL DISORDERS OF THE MUSCLES

The congenital malformations of muscles consist of defects and the absence of the whole, or of part, of a muscle.

The muscular defects of greater importance are those that involve (1) the pectoralis, (2) the trapezius, (3) the serratus anterior and (4) the quadriceps femoris

These muscular defects are easily recognized by inspection and palpation of the region of the muscle, and, more especially, by functional tests

Anomalies. The origins and the insertions of muscles vary within certain recognized limits In addition to these variations, muscles may be present which have abnormal relations or attachments In an occasional individual a muscle may be present which is of no use to him but which is present in other primates as a useful muscle for example, elevator of clavicle, and sternalis and tail muscles. Vestigial muscles are often present; for example, muscles for movements of the ear and scalp

Sometimes a whole or a part of a compound muscle is lacking because of *agenesis* Almost any muscle in the body may be absent or defective, but there is a selective incidence in these ageneses and defects.

Some part of the pectoralis major or minor muscles may be absent, the sternocostal part of the pectoralis major is that most commonly lacking The trapezius, quadriceps, [illegible] sterno-

[illegible] ntly present In rare instances several members of a family may present the same peculiarity of absence or defects of muscles

Congenital Clubfoot. *The deformities of the feet which are of congenital* origin are talipes equinus, the plantar flexed foot; talipes calcaneus, the dorsally flexed foot; talipes varus, the inverted and adducted foot; and talipes valgus, the everted and abducted foot The commonest type, however, is talipes equinovarus, in which the foot is plantar flexed and inverted. In most instances the condition is bilateral

Macklin stated that this condition is inheritable and dependent on a recessive *factor* or on multiple factors and since most of these patients are males, a sex-linked factor is suspected The deformity often occurs in otherwise healthy babies

In the common type of talipes equinovarus the foot is inverted and flexed so that the plantar surfaces of the two feet may be brought into contact The attempt to manipulate the foot into normal position is resisted by the ligaments and by the shortened tibial muscles. The tendons are displaced, the shortened muscles are fibrotic and atrophied, and the bones of the ankle and foot have come to be deformed as the result of growth in the malpositions imposed on them.

The diagnosis is obvious. Differentiation from acquired clubfoot caused by the

Myotonic Dystrophy (Myotonia Atrophica) This is a rare type of heredofamilial degeneration of selective atrophy of muscles, myotonia, cataract, alopecia, atrophy of the sex glands, and premature senility The condition is generally regarded as an independent disease, although it appears to bear some relation to myotonia congenita and to the muscular dystrophies (Ford).

The onset of symptoms is usually between the ages of 20 and 35 years, but it may occur in childhood The first symptoms may result from wasting of the muscles or from myotonia. The muscles which are first attacked are the facial, especially the orbiculares of the eyelids and the mouth, the masseters and temporals, the sternocleidomastoids, the extensors of the forearms, vasti of the thigh, and the dorsiflexors of the feet. In some cases the tongue, soft palate, pharynx and vocal cords are affected Speech is characteristically low-pitched, monotonous and often nasal The hard palate is very high and narrow, and the face is long and thin These patients are usually dull in mentality and are often definitely feeble-minded

The myotonus is always present It is easily elicited by having the patient grip the examiner's hand with maximal force and then open the fingers as rapidly as possible. It will be seen that the flexors do not relax for a second or more after the extensors begin to contract There may also be difficulty in opening the eyelids after closing them tightly, cramping of the feet on attempting to run, and stiffness of the jaw muscles when chewing. Often repetition of the movement several times will result in disappearance of the myotonus Sudden falls may occur as a result of general myotonus, provoked by an effort to run or by an emotional stimulus.

Ford observes that when there is characteristic distribution of the muscular wasting, the myotonus, the cataracts, the characteristic baldness, the testicular atrophy, and the appearance of premature senility distinguish this disease from the muscular dystrophies, and in the presence of these findings the diagnosis is certain.

The disease is incurable but may permit of survival for many years, for in many cases it progresses very slowly

Myotonia Congenita of Thomsen. This is a heredofamilial disease which becomes apparent very early in life, and is characterized by a tendency to myotonia and often by a bulky musculature as well as by various mental disturbances. The cause is unknown The disease is usually present in several members of a family, and may be traced through a number of generations. It affects males and females alike, and may be transmitted by either sex. This disease may behave as either a dominant or a recessive characteristic

The onset is in childhood It is not unusual for the symptoms to increase in severity about the age of puberty The first symptom complained of is an inability to let go quickly of an object which has been grasped firmly. When the patient suddenly rises or starts to run, the muscles become rigid, so that the patient may be unable to take a step for some seconds, or may even fall helplessly to the ground. After the movement has been repeated several times, the rigidity slowly wears off, and the patient then is able to contract and relax the muscles normally. A sudden fright, a loud or an unexpected noise, great anger or mental distress is almost certain to produce general rigidity in affected persons. Cold weather also accentuates the myotonia

The myotonus may be found only in the legs or in the arms. The facial, ocular and tongue muscles may be affected Myotonia may be active or latent Latent myotonia may be elicited only by percussion, by electric stimulation or by causing the patient to sneeze (use snuff). In some patients, emotional reactions are the most effective stimuli.

The muscles are almost always bulky, even suggesting a mesomorphic somatic type or hypertrophy. Strength and endurance are not diminished, and it is possible for these patients to take long walks or to dance for hours

When atrophy is the main lesion of the muscle, there may be resemblance in the findings to those present in lower motor neuron lesions A discussion of these relationships is to be found under Lower Motor Neuron Lesions, p. 331.

SYMPTOMS. The insidious onset may occur at any time during childhood. The parents usually complain that the child has a clumsy gait, that there is difficulty going upstairs, and, not infrequently, it is noticed that the abdomen is unduly prominent. The essential symptoms include progressive weakness and wasting of certain muscle groups. first the muscles of the shoulder girdle and the pelvic girdle, and later the muscles of the upper arm and the thigh. The wasting may or may not be preceded by pseudohypertrophy.

EXAMINATION As a result of weakness of these muscle groups a number of clinical signs may be elicited which are characteristic of the dystrophies. Weakness of the muscles which fix the scapula, namely, the serratus magnus, trapezius and rhomboids, results in winging of the scapula or displacement of the vertebral border of the scapula from the thoracic wall so that it stands out like a wing whenever the patient attempts to elevate the arms

As a result of weakness of the pelvic girdle and hip muscles the patient, usually a child, stands with the pelvis tilted forward, abdomen and buttocks protuberant, and a marked increase of the lumbar lordosis. In walking, the trunk is swung from side to side as a result of weakness of the abductors of the thighs, chiefly the glutei medii. The gait is not unlike that of double congenital dislocation of the hip. Children who can walk fairly well on level ground experience great difficulty in going upstairs or stepping upon a chair. In getting up from the floor the child turns over on the face, draws up the knees and gets up on the hands and knees Next, the legs are extended so that the child is resting on hands and feet with bent knees. The last maneuver is to work the hands back to the legs and, by grasping the legs at higher and higher levels, to push the trunk erect by the arms When the process extends below the knees, the dorsal flexors of the ankles are affected before the extensors, so that the foot is maintained in the equinus position The knee jerks are lost early, but the ankle jerks persist until late in the course of the disease Severe contractures often develop, especially in the flexors of the hip and the extensors of the ankles, and even deformities of the bones may occur from the long-standing loss of muscle balance. Sensory disturbances are absent, and there is no disturbance of sphincteral control In uncomplicated cases there are never any fibrillary or fascicular twitchings

The rate of excretion of creatine is abnormal in adults In all patients who have muscular dystrophy the rate of excretion of creatinine is normal or increased.

The roentgenologist may recognize a conspicuous streaking of the soft tissue shadows of affected muscles There is a delayed appearance of centers of ossification in the epiphyses of the long bones and in the bones of the hands Demineralization of the bones may be observed

DIAGNOSIS The diagnosis of muscular dystrophies is usually obvious However, there may be difficulty at times in differentiating Werdnig-Hoffmann muscular atrophy, amyotonia congenita, progressive neuromuscular atrophy, amyotrophic lateral sclerosis and polyneuritis The course is usually very slow, and many patients survive for 10 to 30 years after the onset of symptoms.

Muscular dystrophies occurring in men and women between the ages of 40 and 55 years may be observed The women are often beginning the menopause at the time of onset. In these there is no genealogic history of similar affections.

The disease begins by weakness and shrinkage in the size of the affected muscles. The manifestations may be of the facioscapulohumeral type, or the face and the shoulder girdle may escape and the muscles of the buttocks and thighs be largely affected In rare instances there is a hyperfunctioning of the thyroid gland.

In some instances the disease progresses to a fatal termination; in others, the symptoms may become arrested, or there may be improvement or even partial recovery.

Epidemic Myalgia. The disease is known also as pleurodynia, devil's grip and Bornholm disease The etiology is unknown. The disease occurs in epidemics and affects children and young adults. The disease seems to spread by contact, and it is not unusual for all the children in a family to be attacked at the same time. The incubation period seems to be between 2 and 4 days.

Pain develops in the muscles of the back, shoulders, abdomen and hips. Pain in the muscles of the thorax and the diaphragm is the first and often the most prominent symptom. There is pain on inspiration, and consequently respiration is shallow and rapid The pain is present also in the muscles of the back, shoulders, abdomen and hips. The more acute pain lasts as a rule only 1 or 2 days, but tenderness may persist somewhat longer. There is only slight fever. Hiccough is present in some cases.

The affected muscles are tender to pressure. There may be localized swellings There is mild leukocytosis and an excess of eosinophils. In the presence of complications there may be found a dry pleurisy, pneumonia and otitis media. Orchitis is occasionally present.

The diagnosis cannot be made except during an epidemic The differential diagnosis comprises the consideration of pleurisy, appendicitis and dengue fever.

Relapses occur in almost one fourth of all cases, and second attacks are common The disease is never fatal, and there are no residua

Dermatomyositis. This is an acute or subacute inflammation of the muscles associated with edema and dermatitis which usually terminates fatally. The involvement of muscles is widespread, it consists of muscular firmness and stiffness, proliferation of interstitial tissue and fatty degeneration.

The disease commences with stiffness, soreness and tenderness of the muscles of the extremities. The trunk muscles may be involved early. The skin over the affected muscles is edematous and often contains erythematous, urticarial or erysipelatoid eruptions. Loss of sensations of the skin is common

The course of the disorder is rapidly progressive, it is fatal in 1 to 3 months and death often follows involvement of the muscles of deglutition or respiration. If recovery should occur, atrophy of the muscles ensues.

Tuberculosis. The contractile tissues of muscles rarely show tuberculous lesions, so that one may speak of an "immunity" of muscles to tuberculosis

Parasitic Infections. These include (1) trichinosis, (2) echinococciasis of muscle and (3) cysticercosis of muscle These conditions have been described in connection with the respective parasites The diagnosis is established by muscle biopsy

TRAUMATIC DISEASE OF MUSCLES

Sudden and violent stretching of a muscle may produce rupture of a tendon or a muscle This causes acute pain The ruptured belly of the muscle may be displaced in the direction of the remaining attachment, and when the muscle contracts, the displacement becomes more evident The muscle exerts no motor effect, but can be seen to contract voluntarily Rupture of the tendon of the long head of the biceps is perhaps the commonest rupture of a tendon In the same way the belly of the muscle may be torn Rupture of the plantaris muscle is apparently not very rare and may occur without violent exertion In some cases violent exertion may cause rupture of the sheath of a muscle A muscle hernia develops as a result, which disappears when the muscle contracts The groove resulting from rupture of the muscle may be palpated. When the muscle contracts, a swelling appears on either side of the groove.

The diagnosis is not difficult if the myotonia is elicited. This condition rarely causes severe incapacity and does not progress. Wolf has shown that quinine will abolish the myotonus of myotonia congenita.

Sleep Paralysis (Dead Asleep) Sleep paralysis is frequently associated with narcolepsy, and attempts by some patients to ward off an attack precipitate an attack of helplessness However, sleep paralysis accompanying natural sleep is a benign condition, probably resulting from a dissociation of the components of sleep. It should be differentiated from familial periodic paralysis. The patient is assured that although the disorder is alarming it is always of short duration and does not result in permanent paralysis or any other disease. Usually just a slight touch suffices to dispel sleep paralysis.

INFECTIONS OF MUSCLES

Intramuscular Abscesses. Acute pyogenic infections of muscles usually result from (1) extension of an infection from the skin above or the bone below, (2) the lodgment of bacteria or infected thrombi or (3) necrosis of tissue and formation of abscess from intramuscular medications.

The symptoms of an intramuscular abscess are pain, swelling, redness and increase in local temperature. Fever often is present There is often a fluctuant mass below the skin and subcutaneous tissue.

The diagnosis is usually obvious, for almost all of these abscesses result from intramuscular medication. The history and the findings are definite.

Local Myositis. Local myositis is often a complication of acute rheumatic fever and is then known as rheumatic myositis. In the acute stage the inflammatory exudate in the muscle can be felt as a firm mass. Later on, this may be followed by the formation of scar tissue (chronic myositis) or by atrophy of the muscle

Gonorrheal myositis may be associated with gonorrheal arthritis. The muscles near the affected joints are most often affected. Occasionally *syphilitic myositis* is met with, in the form of an infiltrating inflammation or of a gumma The so-called *myositis fibrosa* is an end stage of various forms of acute myositis (infectious, traumatic, parasitic). Local ossification of muscle may occur occasionally

Nodular Myositis. Nodular myositis often is present in rheumatoid arthritis. However, nodular myositis is a comparatively common condition in a wide variety of diseases and it is of no diagnostic value in cases of rheumatoid arthritis

Myositis Fibrosa. Myositis fibrosa is a subacute or chronic inflammation of the muscles occurring either locally or generally. It is associated with slight constitutional symptoms, and eventually ends by the replacement of the muscle fibers by connective tissue However, there are many similarities between myositis fibrosa generalisata and progressive muscular dystrophy. The former is essentially a degenerative and not an inflammatory lesion of the muscles. It is not a separate clinical and pathologic entity but is one form of progressive muscular dystrophy.

Disseminated foci are found in which the muscle fibers are undergoing hyaline and vacuolar degeneration. The blood vessels are thickened

The disease begins in the thighs or calves by shortening and inelasticity of the muscles, so that movements are limited in range There are no constitutional reactions such as are observed in dermatomyositis. Gradually the muscles of the hips, abdomen, spinal column, thorax and neck are involved The arms and face are usually affected very late. In some cases the process is generalized and symmetric and is diagnosed *polymyositis*. It may occur asymmetrically and locally.

The physical examination in the beginning reveals an extra firmness of the affected muscles In advanced stages of the disease there are contractures which fix the body and extremities in a position of flexion. The tendon reflexes of the affected muscles are diminished or lost No reduction of sensibility is found The diagnosis is based on the results of biopsy studies

Myasthenia gravis is characterized by weakness and by abnormal fatigue of the striated muscles which is not constantly associated with any demonstrable anatomic lesions.

PATHOLOGY. In some instances the thymus is found to be abnormal, although the abnormality is neither constant nor specific. The thymus may be enlarged; it may be small, degenerated and cystic; or it may have undergone neoplastic changes. The neoplastic change has the appearance of a lymphosarcoma No definite lesions have been demonstrated in the muscle fibers or in the nervous system

Myasthenia gravis occurs at all ages Ford recorded an infant of 18 months who had the disease. There is no evidence of morbid heredity

SYMPTOMS In many cases the symptoms of myasthenia gravis are manifested without apparent cause, and in many others the disease follows a respiratory infection such as influenza or bronchitis.

There are abnormal fatigability and weakness, and finally paralysis of the striated muscles As a rule the muscles innervated by the cranial nerves are affected first, and often dysphagia may be a presenting symptom. Often, however, diplopia is the first symptom, which may accompany or be followed by the appearance of ptosis of one eyelid or both eyelids and by some limitation of ocular movement. The patient may complain of being unable to look up, and thus upward rotation of the eyeball is limited before any other movement is impaired The palsies of fatigue do not correspond to the distribution of any single nerve The pupils react normally. In the morning the patient is refreshed and more alive than at any other time of the day As the day passes, the lids droop and by evening the patient cannot hold the eyes open sufficiently to walk safely Weakness of the bulbar muscles commences shortly after the ocular muscles begin to tire. The voice becomes weak, and persistence in talking results in a nasal and hoarse voice

EXAMINATION Mental alertness is maintained Muscular weakness, as implied by the symptoms, is revealed on examination The jaws grow tired when the patient chews. The face is relaxed, the eyelids cannot be firmly closed, and the corners of the mouth droop The neck grows weak relatively early in the course of the disease and may become so weak that the head cannot be lifted from the pillow. Weakness of the bulbar and oculomotor muscles can be demonstrated before the extremities are affected. The patient eventually becomes too weak to walk or stand The tongue cannot be protruded and articulation is difficult or impossible At this stage of the disease respiration becomes difficult Death may result from failure of respiration within a few hours Except for the muscular atrophy due to disuse, none is present which can be determined with certainty

The muscles are atonic and soft The tendon reflexes are reduced, or abolished, in those who have advanced weakness. In all instances of the disease the tendon reflexes are usually normal at first, but on repeated elicitation the muscle becomes fatigued and finally the reflexes disappear The heart muscle and smooth muscle are not affected at all or only to a very limited extent. Neither the special senses nor other modalities of sensibility are altered in any way

The abnormal excretion of creatine in the urine and the diminished excretion of creatinine are regarded as secondary effects of loss of muscle function since these findings are present in other diseases affecting the muscles Hypoglycemia too must be regarded as secondary

An enlargement of the thymus can be demonstrated in some instances on physical examination or roentgenologic examination. Enlargement of the thymus has been considered etiologically important by Eaton

DIAGNOSIS A diagnosis of myasthenia gravis can be made when there is a definite abnormal weakness of the striated muscles, usually beginning in the ocular or bulbar muscles, and finally becoming generalized, provided there have been remissions and exacerbations of the weakness The abnormal weakness of the muscles is

The history and the findings are diagnostically conclusive.

As the result of direct trauma all or a part of a muscle may be ruptured. For instance, a part of the quadriceps femoris muscle is often ruptured from the trauma of falling forward and astride the steering wheel of an automobile when the overturning car comes to a sudden stop.

HERNIA OF MUSCLE

Hernia of a muscle, due to a defect in the aponeurosis that permits a mass of muscle to bulge through it on contraction, may follow trauma, but it often results from congenital fascial defects

Hernia of a muscle is diagnosed by observing and palpating the muscle during voluntary contractions.

Fascial Hernias of the Legs. Fascial hernias of the legs occur unilaterally and bilaterally in the muscles of persons whose legs have been exposed to severe chronic strain, such as athletes, skiers, mountain climbers, foresters and foot soldiers who have exercised in hilly or mountainous country.

CONTRACTURE OF MUSCLES DUE TO CIRCULATORY DISTURBANCE

Volkmann's Ischemic Contracture. The most serious and one of the commonest types of traumatic injury from ischemia is Volkmann's ischemic contracture However, comparable contracture may occur as the result of circulatory disturbances in compressed, injured muscle in any part of the body

It is generally accepted that circulatory disturbances are responsible for ischemic contractures In Volkmann's contracture the application of tight splints is usually held to blame However, hemorrhage and edema under the fascia in the antecubital space could compress and obstruct the blood vessels there and produce the contracture even if a cast to the arm had been originally correctly applied. The application of a tourniquet or occlusion of the large vessels of the arm may cause the contracture

In Volkmann's contracture there is at first edema, followed by necrosis of the muscle fibers. The fibers are gradually broken down and replaced by connective tissue. The muscle becomes a mass of scar tissue which is adherent to the skin, the tendons and bones.

Volkmann's contracture is found almost exclusively in the muscles of the forearm which flex the fingers and wrist. It follows severe injury to the region of the elbow joint, such as fracture of the lower end of the humerus or of the bones of the forearm. Application of casts which are too tight, a cast made too tight after application by hemorrhage under the fascia, and occasionally application of a tourniquet are the common causes of ischemic contractures Ischemic contracture is very painful and is characterized by pronounced swelling and cyanosis of the fingers

On examination the fingers are cold and blue. Later the skin is drawn tight and is adherent to the subcutaneous tissues and shrunken muscles. The fingers and perhaps the wrist are flexed so strongly at the distal joints that the nails may press into the palm, but the proximal joints are extended. The thumb may or may not be affected. The atrophy and induration are mainly of the extrinsic and intrinsic flexors of the hand and fingers

The diagnosis in the fully developed condition is obvious If the condition can be recognized before irreparable damage is done, the splints should be removed at once. If the circulation does not improve satisfactorily, an incision should be made into the antecubital space and the blood clot removed The prognosis is bad.

TOXIC AND METABOLIC DISORDERS OF MUSCLES

Myasthenia Gravis. Synonyms for myasthenia gravis are asthenic bulbar palsy, bulbar palsy without anatomic basis, myasthenia gravis pseudoparalytica and Goldflam's disease.

The Tic Diseases. A tic is a co-ordinated muscular movement that has become imperative, a functional disorder. The movement may correspond to that of a reflex, defensive or expressive type. The tic is response to an irresistible impulse to movement which makes the patient uncomfortable until the action is performed. It is brief, may be violent, repetitious, and limited to a single movement, or it may be characterized by a multiple series of movements.

Isolated Tics. These tics are commonly present in the facial muscles and represent specific acts such as sucking, licking and biting Scratching and rubbing, particularly of the nose or face, may represent a tic.

Generalized Tic. The disease commences as a form of facial tic—blepharospasm, or *distortion of the mouth—or with a head-nodding tic. Later, stereotyped* tics in the extremities appear Practices without reason or emotional urge are indulged in, such as grabbing of the nose, pulling the chin, or throwing the head to the side, hand-clapping and foot-stamping. In some instances the tics seem to be part of a psychasthenic state, in others, of a dementia praecox. A generalized tic once manifested does not stop.

Generalized tic is distinguished from Sydenham's chorea, from hysteria and from double athetosis These patients are usually schizophrenics.

Paramyoclonus Multiplex. The disease is known also as myoclonia, polyclonia and Friedreich's myoclonus The clonic contractions cause short, quick jerks of the extremities, not involving synergistic muscle groups, and varying in number from a few to 100 per minute. The muscles often involved are the brachioradialis, biceps, trapezius, quadriceps femoris and semitendinosus The contractions disappear in sleep The deep reflexes are exaggerated

The disease must be differentiated from the tic diseases, hysteria, petit mal and chorea chronica

Writers' Cramp. Persons of various occupations are prone to a disturbance of special, skilled, co-ordinated muscular movements used in performance of their work.

Writers' cramp develops in psychoneurotic patients The disturbance commences with an abnormal fatigability on writing; later there is a feeling of cramp in the muscles The writing becomes abnormally irregular, almost illegible, especially when the writer is under observation Results of physical examination of the nervous system may be negative except for the presence of psychoneurotic signs.

Writers' cramp is distinguished from agraphia, paralysis agitans, hemiplegia, tabetic ataxia beginning in the upper extremities, familial and acquired intention tremor, and multiple sclerosis

TUMORS OF THE MUSCLES

Tumors of muscles may be benign or malignant The benign tumors include lipomas, fibromas and osteomas The malignant tumors include, as primary tumors, angiomas and sarcomas, and sometimes, as a secondary tumor, carcinoma. Tumors of muscles should not be confused with myositic indurations, tuberculosis, gumma or parasitic invasions

Desmoid Tumors of Muscles (Fibromas). A desmoid tumor may be defined as a very hard tough fibroma Multiple desmoid tumors may occur in striated muscles, especially in the anterior abdominal wall However, these tumors either singly or multiply occur elsewhere in the body.

That these tumors are due to trauma (accidental, operative, or the physiologic trauma), combined with an unknown individual predisposing factor, appears to be the most logical theory of origin These tumors do not undergo metastasis nor do they endanger life, however, they do tend to recur locally *Diagnosis is made by* finding a fibrous tumor in a muscle, the tumor is fixed by contraction of that muscle. Biopsy is indispensable for diagnosis.

revealed by an increase of symptoms in the evenings and by fatigue in repetition of movements of affected muscles. An improvement in the symptoms which follows the injection of neostigmine (prostigmin) is of diagnostic value, for such always occurs in myasthenia gravis, and never so dramatically is improvement witnessed in other conditions Myasthenia gravis is rare in childhood, and in this period the diagnosis must be made with caution

Quinine sulfate will precipitate the symptoms of myasthenia gravis. Curare in very small doses is used as a test for myasthenia gravis. Patients who have this disease are very sensitive to curare and for this reason this drug should not be used by those who have not had supervised experience in its use When curare is used as a test for myasthenia gravis not more than one twentieth of the curarizing dose is employed The test is positive if great muscular weakness is produced by the administration of curare

There is no curative treatment at present. Prostigmin (5 to 15 mg doses) is of great value but its effect is purely symptomatic. The effect of each dose lasts about two hours

In some instances the symptoms advance rapidly and death supervenes within a few months In others, in which symptoms are definite, there is a tendency for them to remain stationary for a long period. In some instances there are recurrent exacerbations with complete remissions between.

OSSIFICATION IN MUSCLES

Hematomas and granulation tissue resulting from inflammatory processes in muscles may eventually become ossified. Bits of periosteum torn from the bones as a result of trauma give rise to formation of new bone Long-continued trauma of a milder type may also lead to bony deposits in the muscles or tendons For example, plaques of bone are found in the adductors of the thighs in individuals whose occupation requires daily horseback riding Extensive bony processes sometimes appear in the muscles of the lower extremities in severe spastic paraplegias of long *duration. These conditions are localized and do not progress beyond local limits.*

Progressive Myositis Ossificans. Progressive myositis ossificans is a generalized ossification of the skeletal muscles which is dependent on some inborn defect. The etiology is unknown (see also page 1535)

In the beginning there is muscle edema, and often there are hemorrhages The onset begins before the tenth year There is a local, firm, nontender swelling situated in the muscles of the trunk or back of the neck The skin may be slightly red and tender The swelling slowly disappears, leaving a firm small region in the muscle which eventually becomes bony In time successive swellings develop, leaving a bony deposit.

When the disease is fully developed, it can scarcely be confused with any other condition The roentgenographic appearances are characteristic.

In those who survive long enough the disease progresses sufficiently to produce invalidism and death from inanition or fixation of the respiratory apparatus

MUSCULAR DISORDERS SECONDARY TO DISTURBANCES OF INNERVATION

These disorders include (1) the muscular atrophies due to lesions of the lower motor neurons and peripheral nerves, (2) the muscular atrophies due to disuse and

[illegible]

otor neurons and peripheral

ies of muscles from disuse

occur when a joint is mobilized as by a plaster cast or ankylosed

The hyperkinesias comprise the tic diseases, choreas and the occupational neuroses.

wasting, small groups of muscle fibers show irregular twitchings known as fibrillary twitchings or fasciculation. The degenerating muscle is usually extremely tender to pressure and may be painful and subject to cramps.

During this phase of degeneration in the muscle it may show what is known as the reaction of degeneration. The electric testing of muscular reactions is of no value unless performed by an experienced hand, and it is comparatively rare for this testing to provide diagnostic information that cannot be obtained by other means Of greater diagnostic importance is the fact that apparatus for such testing is not usually available in practice.

It is immediately apparent that *lesions of the lower motor neuron* and the neural or *peroneal muscular atrophy* have symptomatically much in common. A neural or peroneal atrophy is characterized by a slowly progressive palsy with flaccidity of muscles. A *hypertrophic interstitial neuritis* causes the same symptoms but can be recognized by the palpable thickening of the peripheral nerve trunks. In either disease more than one member of a family may be affected

In the descriptions of the diseases of the muscles it was recorded that the *myopathies* are characterized by chronic and progressive wasting of the muscles and frequently appear in several siblings. The muscles of the pelvic girdle and the shoulder girdle are selected by this process and the muscles of the proximal parts of the extremities are also affected early in the course of the disease.

Muscular atrophies and flaccid paralysis are due either to a lower motor neuron lesion or to lesions in the nerve or the muscles. When the lesion is situated in the muscle, it is comparable to the lesions present in the muscular dystrophies. The muscles are soft, waste away, and throughout the illness lack tone There is absence or diminution of the tendon reflexes The plantar response is flexion. When the lesion is in the lower motor neuron, tests of electric excitability reveal loss of faradic reaction and a slow galvanic response, that is, the reaction of degeneration. When the lesion is in the muscles, there is only a quantitative reduction of irritability. Atrophy of the muscles must be distinguished from defective development When the lesion is situated in a peripheral nerve trunk there are muscular atrophy and sensory changes in the skin.

Among the *congenital conditions* giving rise to a generalized chronic congenital weakness and loss of tone of the muscles are amyotonia congenita and atonic cerebral diplegia. Both of these diseases are uncommon

Among the conditions causing flaccid paralysis at birth are rupture or stretching of the brachial plexus during birth which frequently causes paralysis of the fifth and sixth roots of the plexus with loss of abduction and external rotation at the shoulder, of flexion at the elbow and of supination of the forearm. Injury to the upper roots of the brachial plexus during birth may cause paralysis of the diaphragm on one or both sides

Because of the high incidence of local palsies with atrophy, as the result of injury to the spinal nerves, these are always considered in any diagnosis when these findings are present The nerve may be lacerated by fragments of bone, injured by pressure of a tight splint or compressed by formation of scar tissue or callus Falls which depress the shoulder may cause brachial plexus palsy.

Acute Anterior Poliomyelitis (*Infantile Paralysis, Heine-Medin Disease*) Poliomyelitis is an acute infectious disease that is caused by the smallest in size of the filtrable viruses which has sufficiently distinct properties to permit its identification with much certainty.

There are three immunologically distinct types of the poliomyelitis virus: type 1 (Brunhilde), type 2 (Lansing) and type 3 (Leon). These types are so sharply

Venous Angiomas of Skeletal Muscle. In some patients angiomas of the muscles are true tumors. They may grow and exhibit the characteristics of a malignant neoplasm. In others angiomas are malformations, masses of swollen blood vessels which are of congenital origin or clearly related to injury. Their course is variable; many remain stationary; some disappear spontaneously. The angiomas of congenital origin do not produce symptoms until late childhood or early adult life

Venous angiomas of skeletal muscle occur with about equal frequency in the two sexes In most cases the malformation is first observed during childhood or early adult life

The symptoms commence with pain and swelling related to muscular movement. The tumor and thus the symptoms may occur in any striated muscle, although the most frequently involved muscle seems to be the quadriceps extensor. Venous angiomas vary in diameter from less than 1 inch (1 to 2 cm) up to 4 or 5 inches (10 to 12 cm.) or more.

Paresthesias, numbness and periodic or constant swelling are commonly present There is occasionally fixation of the overlying skin which exhibits some degree of bluish discoloration The mass is soft and movable; rarely is it firm and fixed. Seldom are pulsations or *bruits to be made out unless there are free arteriovenous com*munications

In addition to the clinical examination there are three procedures which are diagnostically helpful (1) exploratory puncture, with aspiration of normal blood, (2) the intravenous injection of radiopaque solution, and (3) roentgenologic examination *The diagnosis is based on the history and the findings on examination*

LOCOMOTION AND THE NERVOUS SYSTEM

In man the basic structures subserving locomotion, consisting of bones, joints, muscles and nerves, have not changed greatly since he began to walk on his hind legs. The great change has come about through freeing the front quarters of their main responsibility in locomotion. The front quarters, having been emancipated from responsible locomotor functions, come more under the influence and guidance of the cerebral cortex than do the front quarters of the animals who use them solely for locomotion. It therefore has been necessary to consider the organization of the motor nervous system as such after the description of the diseases of locomotion as they occur in bones, joints, muscles and peripheral blood vessels.

The neuron concept of the development and structure of nerves and nerve fibers repudiates the idea that nerve fibers develop from cell chains or a syncytium, and holds (1) that all axons and dendrites are true outgrowths from nerve cells and (2) that each neuron remains throughout life a discrete structural and functional unit Critical cytologic observations favor discontinuity where process and cells of different neurons come into functional contact Collateral evidence is afforded by the behavior of neurons after severance or injury, the fibers distal to the point of section (and thus isolated from their cell bodies) degenerate, whereas the central stumps live and regenerate

THE MOTOR NERVOUS SYSTEM

On the basis of structure and function, the motor nervous system is divided into five components, namely, (1) the lower motor neuron, (2) the upper motor (pyramidal) neuron, (3) an extrapyramidal system of neurons, (4) the cerebellar system and (5) the frontal cortex (eupraxic functions) *immediately anterior to the* motor cortex.

The Lower Motor Neurons and Locomotion. Any lesion which interrupts the lower motor neuron deprives a muscle of its nerve supply and causes it to become flaccid and completely paralyzed, to lose its tendon reflex and to waste. Fibrous changes take place in its structure, *it shortens and undergoes contracture.* In cases in which the interruption of nerve supply is incomplete during the active process of

are no data to support a contention that dietary deficiencies predispose to poliomyelitis. On the contrary, it often seems that the victim of poliomyelitis is well nourished, perhaps even better nourished and developed than the children who do not get the disease.

PATHOLOGY Focal areas of injury are present in the pons, brain stem, motor cortex and meninges Injuries have been found in the dorsal root ganglion There are irritation and hyperplasia in mesenteric and enteric lymphatic tissue which are especially conspicuous in children

In the spinal cord the lesions are most prominent and extensive in the cervical and lumbar enlargements, especially in gray matter of the anterior horns. It is the destruction of ganglion cells in these areas that is responsible for the clinical expression of the disease. Pathologically the disease is associated with destructive lesions in the gray matter of the spinal cord and brain, the white tracts being largely spared

Depending on the severity of the disease process or the situation of the main involvement in the spinal cord, several types of poliomyelitis have been designated In the *abortive* type there are constitutional symptoms without symptoms of invasion of the central nervous system. In the *nonparalytic* or *meningeal* type there are constitutional symptoms of the abortive type plus fever, drowsiness and signs of meningeal irritation and an increase of cells in the spinal fluid No paralysis occurs in these cases. The *spinal* type embraces the classic forms of the disease When symptoms indicate involvement of the medulla, pons or midbrain occurring alone or combined with spinal symptoms, the disease is designated the *brain-stem* type.

SYMPTOMS In most instances of poliomyelitis the first symptoms are referable to the gastrointestinal and respiratory systems singly or combined There are fever, headache, catarrhal inflammation of the respiratory passages and often diarrhea The temperature reaches its peak in the afternoon, 100 to 103 F (37.7 to 39.4 C), and shows a tendency to drop in the morning In from 1 to 3 days symptoms referable to the central nervous system appear. In a few cases a remission follows the initial symptoms Then the temperature rises again and paralysis may or may not supervene. An occasional case of poliomyelitis is observed without initial symptoms and is characterized by an abrupt appearance of paralysis.

Headache is the most distinctive initial complaint in poliomyelitis. This is usually of a severe, generalized, unrelenting type, which is a rare symptom in the illnesses of childhood In addition to headache and fever there are nausea, vomiting, anorexia, stiff neck, stiff back, painful extremities and general malaise with listlessness The muscular pains may be severe Sore throat may be an early complaint. The absence of inflammation of the throat in patients who complain of sore throat suggests the possibility of a painful throat of neuritic origin The complaint of sore throat occurs more frequently in those in whom bulbar paralysis develops than in other patients. There may be drowsiness and apathy Irritability alternating with drowsiness is common Sometimes the drowsiness deepens into stupor or in fatal instances into coma Within a short time signs and symptoms indicative of involvement of the segmental motor apparatus develop. The fever lasts for 4 or 5 days and falls by lysis, although it may persist for several weeks The prostration and drowsiness may continue for several days after the fever has ceased

In the cerebral type there is a profound stupor, both with and without spinal palsies Included here also is hemiplegia, the type with an acute febrile onset without spinal palsies (Strumpell's polioencephalitis).

The paralysis remains unchanged for several weeks before improvement commences. The major part of the improvement may be expected within six months, but appreciable returns of tone and muscle power may be observed after the end of the first year. There is atrophy of the affected muscles on the permanency and extent of which depend the spinal lesions The paralysis of groups of muscles imposes the additional handicap of lack of muscle balance. The soft bones of childhood are unable to cope with a lack of balance to carry the body weight, and the ankles,

defined that convalescent serum from one type will not protect against the others and also that the convalescent monkeys which are immune to reinoculation with one type can be reinfected with another type. Many observers believe that in the human being the virus of poliomyelitis is distributed *predominantly in only two systems, the* nervous system and the alimentary tract.

In human infections probably the virus enters the body by way of the mouth and establishes itself throughout the alimentary tract, where *it proceeds to multiply* There is suggestive evidence that the walls of the pharynx and small intestine are among the chief sites of virus multiplication while the virus is in the alimentary tract, and that the feces are the chief means of virus elimination The *virus may begin its* invasion of the central nervous system along the *cranial nerves that supply the* upper part of the digestive tract and thus pass into the medulla. It may enter by way of the parasympathetic system along the vagus from the middle part of the digestive tract into the spinal cord It could pass along the visceral afferent fibers through the *spinal* ganglia or along the visceral efferent fibers from the intestine by way of the abdominal sympathetic ganglia.

Poliomyelitis is cosmopolitan in distribution It occurs in epidemic, sporadic and endemic forms No *race is immune. In the United States it is most prevalent in* Vermont, New York, New Jersey, Nevada and Minnesota. More than three fourths of the sporadic cases occur between June and October, and all the epidemics have prevailed during the warm months of the year

The *disease is contagious,* being transmitted directly by droplet infection by healthy carriers of the virus, by those who are in the prodromal stage, or by those acutely ill with the disease

Children between the ages of 2 and 4 *years are most susceptible to poliomyelitis;* the disease is unusual in early infancy and in adult life. In no age group, however, is there full immunity Blood serum of convalescents, and of many adults who are not aware of ever having had poliomyelitis, contains antibodies, thus indicating that the morbidity rate is much higher than is recognized from the clinical evidence of having had the disease. A high degree of immunity is conferred by an attack of poliomyelitis, since second attacks are exceedingly rare.

The incubation period varies between 7 and 14 days, and often from 1 to 6 days. In Casey's experience the incubation period (calculated from exposure to onset of prodromal period) in 37 instances of epidemic human poliomyelitis varied from 5 to 35 days and averaged 12.2 ± 1.1 days

Casey, Fishbein and Bundesen observed that *multiple cases of poliomyelitis in the family* are the rule rather than the exception when there are other children from about 2 to 9 years of age in the home The disease is less infectious in the older groups. In many instances of poliomyelitis, the disease was so mild that a physician was not consulted Once the disease is present in a neighborhood, there is no evidence that flies and other insects play a major role in the spread of the disease.

Cunning presented a statistical report which completed a four-year nationwide survey conducted by the American Laryngological, Rhinological and Otological Society. This study was based on 36,678 cases of poliomyelitis and 96,379 cases in which *tonsillectomy* had been performed. It failed to reveal any causal relationship between poliomyelitis and tonsillectomy The studies did not indicate that tonsillectomy should be indefinitely postponed in the summer months simply because poliomyelitis is prevalent during this season. The author did not, however, advise operation during any epidemic, regardless of its nature

Clinicians generally agree that a deficiency in vitamins or other essential food elements usually results in a lowered natural resistance to bacterial infections. There is reason to believe that this hypo-immunity is largely due to a reduction in phagocytic functions. In contrast with this general agreement the effect of similar nutritional deficiencies on *antiviral* resistance is still controversial. At present there

are affected in addition to the diaphragm, respiratory failure and death ensue. Intercostal paralysis is recognized by failure of the thorax to expand and by retraction of the lower ribs during inspiration.

Involvement of the muscles which aid in support of the spinal column usually is not detectable until some time after the acute stages of the disease have passed and severe spinal deformities develop

The affected extremities are cold, mottled with a purplish blue color, and slightly swollen.

The brain-stem type of poliomyelitis selects the motor nuclei of the cranial nerves. As a rule, however, the cranial nerve paralyses do not persist. Third and fourth nerve paralyses are common The fifth and the twelfth nerves are usually spared. The facial nerve is usually spared The sixth nerve is the one commonly affected in ocular palsy Paralysis or weakness of the soft palate, the pharynx, and the vocal cords, and irregularities of pulse and respiration are present in tenth nerve involvement The voice is hoarse and swallowing is difficult

There is leukocytosis, the concentration of leukocytes ranging from 15,000 to 30,000 per cubic millimeter of blood, beginning in the prodromal stage and persisting for 6 or more weeks The lymphocytes may be diminished, and thus occasionally the total leukocyte count is normal owing to this reduction of lymphocytes and increase in other white cells

During the first week the cell count of the spinal fluid is often between 50 and 100 or more per cubic millimeter. Lymphocytes predominate in the spinal fluid throughout the course of the illness. In 2 weeks the cell count returns to normal values The globulin content during the first week is normal Thereafter, its value increases and the increase may persist for several weeks to more than a month The content of sugar and chloride is within normal limits.

The spinal fluid is never purulent and yellowish in poliomyelitis. The only time that there is an increased polymorphonuclear leukocyte count in poliomyelitis is during the early stages of the disease, prior to the time when paralysis is present. If the cells are predominantly leukocytes, the probabilities are that bacteria cause the condition, and they can be identified on a stained smear

When there are mixed types of cells and the proportion of lymphocytes is greater than that of leukocytes, either the patient is recovering from an acute infection which might have been pyogenic in origin, commonly an irritation of the meninges, or some disease is developing which ordinarily causes a lymphocytic reaction A second puncture to determine the further progress of the disease is indicated If the ratio becomes more lymphocytic, it is recognized that probably the disease is one causing lymphocytic reaction If the cells are predominantly lymphocytes, it is known that the disease is an encephalitis of some character

The amount of protein present in the spinal fluid gives a clue to the severity of the involvement

Diagnosis The presence of fever, signs of meningeal irritation, flaccid palsies and the changes in the spinal fluid are diagnostically definite.

During the summer any patient from 3 to 10 years of age who has difficulty in speaking, difficulty in clearly enunciating syllables, sounds, words, and especially consonants, or who has any difficulty in swallowing solid foods or liquids, should be s

stag

the disease may be suspected or diagnosed, but when this form occurs sporadically, it cannot be diagnosed.

In influenza there may be a stiff neck, and the gastrointestinal symptoms may be the same as those in early poliomyelitis However, the neurologic and spinal fluid findings are negative

knees, hips and back are forced to become deformed. Paralysis of the intercostal muscles may permit gross deformities of the thorax.

The unaffected muscles eventually undergo contracture. The paralyzed muscles are placed under tension which exerts an injurious effect on them As the result of excessive fatigue and strain, weak muscles may become paralyzed long after the active disease has ceased. In limbs with muscles paralyzed sufficiently to inhibit their use, the bones fail to grow and they undergo decalcification, causing an increased excretion of the calcium in the urine.

EXAMINATION On physical examination it may be observed that the patient lies quietly in bed and does not wish to be disturbed There are irritability and resentment against being moved or handled. The painful sensitivity of the peripheral tissues indicates the presence of spasm, a common and useful observation. Stiff neck, stiff back and shortened hamstrings are familiar examples of symptoms caused by the disease, but muscles elsewhere in the body may also be involved by spasm The muscular tenderness occurs in the nonparalytic as well as the paralytic individuals.

When the examiner places the hand beneath the patient's head and attempts to flex the neck, resistance will almost invariably be encountered as early as clinical symptoms have become manifested. An attempt to flex the body will disclose stiffness of the back When the trunk is flexed, the knees will rise from the bed because of shortness of the hamstring muscles. The stiffness is due to the condition of spasm in the posterior muscles On search, the same hypertonicity and shortening may be found, although less frequently, in other muscles of the body and in all types of cases

The patient may complain of pain in the muscles involved by spasm, or pain may be elicited by gently stretching the affected muscles. Involvement of the muscles of any part of the respiratory mechanism hampers the breathing. Spasm may affect the abdominal muscles.

Spasm occurs more frequently in the paralytic than in the nonparalytic patient. The value of this observation for the purpose of diagnosis is diminished by the fact that paralysis is not a common early condition and may not occur at all Paralysis occurs at some time within 15 days of onset in two thirds of the cases Neither weakness nor paralysis appears as an initial symptom, as a rule, and in only a few cases does this condition develop during the first 24 hours.

Patients who have bulbar symptoms, such as difficulty in swallowing, nasal regurgitation, facial weakness, and difficulty in speech, reveal muscular dysfunction, on the average, slightly earlier than patients in whom the spinal type of paralysis develops

It may be observed that there are twitchings in certain muscles and that in these same segments there is an increase of tendon reflexes accompanied by pain and tenderness. In some muscles the reflexes are diminished or lost and weakness and paralysis are present. The paralysis may be found on the first, second or third day of the illness but it may be delayed until the seventh or eighth day The paralysis may begin in the legs and ascend to involve groups of muscles higher up. It may be observed that the paralysis, after remaining stationary for several days or weeks, has extended once more In the early stages of the disease, ankle clonus or even plantar extension may be found

In the leg the quadriceps femoris, the peroneals, the flexors of the foot and the extensors of the toes are more commonly involved than other muscles The iliopsoas and the gluteals are often selected In the upper extremity the deltoid, the spinati, the flexors of the elbow and the supinators of the forearm are often involved Paralysis of the muscles about the shoulder joint and upper arm is common.

The diaphragm is usually affected in association with paralyses of the arms and the muscles of the shoulder girdle. In cases of diaphragmatic paralysis, breathing is thoracic with the epigastrium retracted during inspiration. If the intercostal muscles

tion with poliomyelitis and has some characteristics in common with that disease. These viruses differ immunologically from poliomyelitis viruses and do not cause the lesions of poliomyelitis when injected into monkeys The role of the newly discovered viruses in the causation of human disease is still uncertain

Tetanus (*Lockjaw*). In contrast to degenerative or destructive lesions of neuromuscular apparatus involving the muscles, as in the dystrophies, or the nerves primarily or the cells of the spinal cord, as in acute anterior poliomyelitis, is the hyperirritability of muscles in tetanus or lockjaw However, the very early manifestation of both of these diseases is muscular spasm.

As a rule, *Clostridium tetani* does not multiply within the tissues except in the presence of necrotic material Thus puncture wounds and buried splinters offer favorable conditions for a focus of this infection The organisms do not reach the nervous system The toxin reaches the nervous system by extending inward along the nerve trunks Once within the central nervous system, the toxin diffuses rapidly However, according to Abel, the toxic conditions caused by tetanus are created by three processes: (1) a local lymph-borne intoxication of the muscles or motor nerve endings, (2) a generalized effect of the same nature due to blood-borne toxin and (3) a series of symptoms due to the action of the blood-borne toxin on the anterior horn cells of the spinal cord (see Chapter 18).

The *incubation period* of tetanus averages about 7 to 8 days but may be prolonged to several weeks or even months in cases in which antitoxin has been administered. One attack does not necessarily bestow immunity

Symptoms. The first characteristic symptom of tetanus is tightness and twitching of the muscles There is trismus of the muscles of mastication The posterior cervical and abdominal muscles are affected early.

In the localized forms of the disease the first symptom is a constant spasm of the muscles in the neighborhood of the wound The spasm extends and frequently involves a whole limb. The symptoms may gradually advance for a week or two and the intense muscular spasm then may persist for two months. Local tetanus is less serious than the general form

Tetanus infections of the face, neck or head may produce a cephalic type of tetanus It begins with spasm of the facial muscles on one or both sides or with involvement of the jaws or pharynx Cephalic tetanus may remain localized or may be followed by a generalized tetanus In a few favorable cases the spasms grow less frequent and severe and the rigidity diminishes in a few days The trismus is often the last sign to disappear Convalescence is slow When the disease is fatal, death occurs in 3 or 4 days In some cases of fulminating tetanus death may result from asphyxia within a few hours The temperature often remains normal until toward the end The development of high fever is a bad prognostic sign

Examination On repeated examinations the tightness of the muscles is observed to increase. Pressure over the affected muscles and efforts to stretch them cause severe pain As the disease progresses, it is observed that the muscular movements grow more and more limited, and finally it is observed that constant and intense contracture of the muscles has developed so that the muscles have become immobile with spasm The spasm progresses successively to the muscles of the spinal column, the abdomen, the thorax and the legs, and to the arms When all the muscles are involved with spasm, the legs are extended, the head is retracted and the trunk is arched backward into a position of opisthotonos The arms are flexed and the fingers clenched The angles of the mouth are retracted (risus sardonicus), the eyelids partially closed, and the eyebrows elevated. By this time the bulbar muscles are affected and dysphagia, aphonia and cyanosis are present.

Owing to sphincteral involvement there is retention of urine and feces. The [illegible] f respiration

[illegible] ecome more frequent and more prolonged The pain is horrifying to the patient, and its apparent

The patient who has rheumatic fever may not be able to move the legs because of pain; the immobilization, however, is voluntary. There are present pain at the insertion of the tendons or in the joints involved, perhaps a cardiac murmur, and a good therapeutic response to salicylic acid.

In postvaccinal encephalitis there are present encephalitic irritability followed by stupor, a history of vaccination, and a relatively low lymphocyte count with an extremely high protein content in the spinal fluid. If the patient is seen at the onset, there are signs of an upper, but not of a lower, motor neuron lesion. Later, during coma, neurologic reactions may be absent.

In lymphocytic choriomeningitis (acute benign idiopathic meningitis, acute aseptic meningitis, benign aseptic choriomeningitis, epidemic meningitis serosa, or serous meningitis), the onset is acute and the progress rapid, and it occurs in any age group at any time and in any locality It is accompanied by headache, muscular pains and sometimes constipation. Neither muscle weaknesses nor neurologic signs are present, except perhaps in a positive Kernig sign and a stiff neck Examination of the spinal fluid reveals normal sugar and chloride, negative reactions to all tests, a meningitic gold curve, a cell count ranging from 20 to more than 1,000 cells per cubic millimeter, 90 per cent of which are lymphocytes, with little or no protein It is therefore evident that it is impossible to separate this disease from an abortive type of poliomyelitis when it occurs during an epidemic of poliomyelitis

The spinal fluid in equine encephalomyelitis usually is clear to ground-glass in appearance and contains from 200 to 2,000 cells per cubic millimeter, mostly polymorphonuclear leukocytes, the globulin is 4 plus.

Tuberculous meningitis in its inception is difficult to differentiate from poliomyelitis. Time may be required for the differentiation A patient who has tuberculous meningitis remains ill for days, with but few symptoms and little or no fever and with no paralysis of muscles. Specific organisms are present in the spinal fluid.

The Coxsackie Viruses. Investigation of small epidemics of poliomyelitis led to the isolation by Dalldorf and Sickles, from fecal specimens of 2 children in the acute phase, of an agent that induces paralysis in suckling mice and hamsters. This paralysis is associated with destructive lesions of skeletal muscles, the central nervous system being unaffected.

Howitt reported isolations of the Coxsackie group of viruses from the secretions or tissues of patients from Alabama, Colorado, Delaware, Florida, Georgia, Louisiana, Oklahoma, South Dakota and Tennessee

The Coxsackie virus may be isolated from human feces, urine, nasopharyngeal or oral washings, oral vesicles, nasal swabs, saliva, sputum, serum, whole blood, cord and brain. The virus has been isolated in sporadic cases and from groups of patients who had variable and ill-defined symptoms such as mild fevers, poliomyelitis-like or influenzal syndromes and occasionally encephalitis

Howitt's study revealed Coxsackie virus in the tissues and secretions of 10 patients whose disease was fatal, in 5 of 10 cases the diagnosis was poliomyelitis. Poliomyelitis virus was recovered also from the spinal cord of 1 of these patients and from the feces of 2 patients who had recovered. Howitt and Benefield were able to differentiate the Coxsackie virus into serologically distinct types by the complement fixation test with filtered muscle antigen. The same test can be employed for determination of the presence of antibodies in human serums. At least two immunologic types of the virus exist The virus has been isolated from the sewage of a number of cities and from flies collected in widely separated areas

Findlay has cited evidence to suggest that Coxsackie viruses 1 and 2 are widely distributed in Great Britain and that some epidemics of Bornholm disease (epidemic pleurodynia) in that country are associated with infection by Coxsackie virus 1 or 2 or closely allied viruses. It is, therefore, apparent that there exists a common infectious disease caused by the Coxsackie virus group that occurs in close associa-

more there may remain a detectable defect in conjugate deviation of the eyes toward the paralyzed side.

The upper part of the face is but slightly weakened. The facial weakness is more evident on voluntary than on emotional movement. At first it may be impossible to wink the eye of the affected side without closing the opposite eye. Voluntary movement is most severely restricted or abolished in the arm. Both the arm and the leg reveal the hypertonicity and reflexes characteristic of an upper motor neuron lesion. There is weakness of trunk muscles revealed by the inability of the patient to sit up in bed and often to turn in bed There is a tendency to fall toward the paralyzed side when standing is permitted or attempted

The affected arm slowly adopts an attitude of general flexion and adduction. The leg develops an attitude of extension and outward rotation. The foot is plantar flexed, and it so remains. The demented hemiplegic patient tends to lie on the contralateral side, which permits flexion of the ipsilateral leg Flexion of both legs ensues because of disuse too of the contralateral leg This attitude of flexed legs becomes fixed unless prevented by braces The addition of braces makes it very difficult to give nursing care

On examination when the hemiplegia has become fully established, the findings are those of the upper motor neuron lesion Isolated movements of the fingers and all skilled movements of the hand, extension of wrist and fingers, extension at the elbow, clenching of the fist, and flexion at the elbow are affected Elevation and adduction at the shoulder are but slightly impaired Dorsiflexion of toes and foot, eversion of the foot, flexion at knee and hip, plantar flexion of foot and toes, and, least severely, extension at knee and hip and inversion of the foot are reduced or abolished.

The movements of the lower part of the face are more severely impaired than those of the upper part. Deglutition is unaffected, but articulation may be transiently or permanently disordered.

The increase in muscular tone is more evident in the musculature of the arms and legs. The increased tone, or spasticity, however, is variable in the muscle groups For instance, in the upper limbs it is most marked in the flexor muscles of forearm and arm and in the adductors of the shoulder In the lower limbs it is characteristically most marked in plantar flexor and extensor muscles Its presence is detected by passive stretching of the muscles and observing an increased resistance. An increased resistance is easily elicited in the knee extensors While the patient is reclining in bed, request him to rest the thigh upon the examiner's forearm; the examiner's other hand grasps the leg just above the ankle and flexes the leg at the knee Slight flexion is normally permitted without marked resistance. However, as flexion is increased, an active resistance develops quickly in the quadriceps muscle, and more force is needed to continue the flexion After the knee is flexed to approximately 45 degrees, the resistance ceases and the rest of the movement is carried out normally In spastic paraplegia it may be difficult to flex the leg passively In instances of mild hemiplegia only mild muscular hypertonus may be appreciable in the flexors of the fingers and in the plantar flexors of the foot

The loss of cutaneous reflexes is not an invariable feature of upper motor neuron lesions. The extensor (Babinski) type of plantar response is present in an upper motor neuron lesion. This reflex may be obtained from both cutaneous and deep stimulation Pinching the skin of the foot or leg, pressure over bony points around the ankle, or a stroking pressure over the shin, may elicit the response. Thus Oppenheim's, Gordon's and Chaddock's reflexes are not more than the extensor plantar response elicited from different parts of its wide receptive field The extensor type of plantar response in those who have paraplegia-in-extension may be accompanied by plantar flexion of the foot and great toe of the opposite side, the so-called crossed plantar response

intensity defies description, for the patient does not lose consciousness. The spasm may be so great that fractures of the vertebrae ensue. A moderate leukocytosis is present. The spinal fluid is normal. The pressure is increased.

DIAGNOSIS. The history of a wound, the trismus, the opisthotonos, risus sardonicus and abdominal rigidity and the tonic muscular spasm persisting between the paroxysms are diagnostic.

There is a mortality rate of less than 50 per cent if patients are properly treated with antitoxins.

In treatment for tetanus an antitoxin is used The American unit of antitoxin is defined as 10 times the least amount of serum necessary to save the life of a guinea pig weighing 350 gm for 96 hours against the standard test dose of toxin The standard dose of toxin is 100 M L D of a standard toxin preserved at the National Institute of Health.

The Upper Motor (Pyramidal) Neurons and Locomotion. It has been indicated in the preliminary definitions that upper motor neurons, at least a few of them, arise from the Betz cells of the cortex and pass uninterruptedly to the anterior horn cells of the cord It is for the purpose of definition that these neurons have been singled out, for in reality the pyramidal system is a twofold communicating system. It is an internuncial path interposed between the distance receptors and their central cortical connections, and the motor mechanisms of the nervous system. Through the pyramidal system pass all the impulses which instigate willed movements of skeletal muscles. These movements are activated and designed by the cortical (frontal lobe) afferent patterns of excitation

As the complexities of the nervous system prevail, it must be added that in the manifestations of the lesion of the upper motor neurons there are evidences also of overaction in subordinate extrapyramidal neurons. This overaction of the extrapyramidal neurons is manifested by spasticity, increased tendon reflexes, clonus, and the extensor type of plantar response These reflex changes have their origin as the result of a loss of influence of the pyramidal neuron The symptoms are often designated release symptoms

Hemiplegia. Hemiplegia represents a common acute or chronic manifestation of an upper motor neuron lesion. Hemiplegia is caused by a lesion of the brain on the side opposite (contralateral side) the paralyzed muscles of the face, arm and leg. Usually developing acutely, it passes through an acute phase and then subsides, leaving the muscles hypertonic or spastic—the spastic phase Initially the onset is sudden and the patient is found unconscious, lying with the head and eyes turned away from the side of the lesion Often there is a slight ptosis of the eyelid on the affected side. The cheek on the paralyzed half of the face flaps in and out with each breath. If the breathing is stertorous, the increased amount of sputum is spattered over the face, clothing or bedding. The entire musculature is flaccid The flaccidity of the affected side of the mouth and the thigh is most noticeable. The paralyzed thigh muscles spread out as the patient lies supine and give this part of the limb a broader appearance than the other one. The tongue may be thrust out toward the hemiplegic side. It is impelled outward by the genioglossus muscle of the normal side. The tongue returns to the mouth within an hour or two except in those patients who remain severely paralyzed The base of the tongue often remains higher on the paralyzed side than on the opposite side

For a week or more the temperature of the hemiplegic half of the body may be from 1.5 to 2 F higher than of the opposite half. Often acute trophic lesions develop: edema of hand and foot with blistering, and bedsores The abdominal reflexes are abolished on the paralyzed side. Only in the most deeply comatose patients are the tendon jerks abolished. The plantar response is extensor on the affected foot The shock usually passes off after a few hours and the patient regains consciousness, and on restoration of consciousness release symptoms appear. The deviation of the head and eyes away from the side of the hemiplegia passes off, but for a week or

be local invasion from osteomyelitis of the vertebrae or from furunculosis with an ensuing septicemia. Purulent myelitis and even abscess of the spinal cord may occur in various types of septicemia, but these are rare

Tuberculous spondylitis may cause sudden paraplegia although, as a rule, the onset is slow.

Acute spastic paraplegias in association with other types of infection such as those due to the viruses of measles, vaccinia, varicella or mumps may appear without any other evidence of involvement of the nervous system An acute paraplegia may follow a febrile illness of obscure nature or may occur without apparent cause.

Paraplegias-in-extension due to pyramidal (upper motor neuron) lesions in the cord develop slowly. The toe begins to drag and it is frequently stubbed The sole of the toe of the shoe is worn on the inner side This difficulty in locomotion is enhanced by the flexion weakness of the leg, and shuffling gait ensues Spasticity develops in the extensor and plantar flexor muscles The plantar response often is extensor in type. The legs come to be rigidly extended and abducted Paroxysms of spontaneous clonus or sudden single extension spasms are experienced

Paraplegia-in-flexion occurs when there is a more complete interruption of conduction of descending impulses in the cord than is present in paraplegia-in-extension

Involuntary flexor spasms increase, and finally the legs come to lie flexed, with the knees pressed against the abdominal wall If the legs are forcefully extended they rapidly resume flexion The extensor type of plantar response may be obtained from the middle of the thigh, downward by pinching or pricking the skin, or deep stroking over bones and muscles The knee jerks, and later the ankle jerks, may diminish and become difficult if not impossible to obtain

The diagnosis is established by the history and the physical findings Identification of the organism by bacteriologic culture is helpful in treatment.

Injuries of the spinal column may involve the spinal cord as a result of hemorrhage or compression by dislocation of intervertebral disks or the vertebrae themselves Often, in instances in which the injury of the cord is due to trauma, dislocation of the intervertebral disks or fracture of vertebrae may not be demonstrable on roentgenologic examination Such lack of evidence of injury is explained by the fact that dislocations of the vertebrae are reduced spontaneously In rare instances dislocation of a vertebra (the first or second cervical) has occurred spontaneously, and such an occurrence may cause paraplegia or may cause sudden death

During the course of *multiple sclerosis,* especially in association with an optic neuritis from the same cause (neuromyelitis optica), a spastic paraplegia may occur In these cases the paraplegia may improve

The diagnosis depends on the association of acute transverse myelitis, optic neuritis, and other symptoms of multiple sclerosis

Paraplegias of gradual onset may be due to *extradural sarcomas and gliomas,* fibromatous tumors of Recklinghausen's disease, syringomyelia, tuberculous spondylitis, and severe kyphosis of nontuberculous origin

The diagnosis of these conditions depends on expert interpretation of myelograms made with experienced hands

Extrapyramidal Neurons and Locomotion. It has been stated that the extrapyramidal tract consists of short neurons intercommunicating with parts of the pyramidal system (upper motor neurons) and that this system is presided over in some degree by the pyramidal system These short tracts connect with the corpus striatum, the substantia nigra, corpus subthalamicum, red nucleus, vestibular and reticular nuclei, and long descending tracts, the rubrospinal, vestibulospinal and reticulospinal

The essential clinical components of the different syndromes of extrapyramidal

When the hemiplegic patient yawns or stretches, as during any forceful or sustained movement of the normal limb, the affected arm tends to extend at the elbow, wrist and fingers, remaining rigidly in this new attitude until the yawn passes off. Simultaneously the leg goes into rigid extension with the foot plantar flexed. These phenomena are not associated movements, but rather are phenomena in the normal maintenance of posture.

Due to the fact that the arm and hand have been freed of locomotor functions, their movements are controlled from the cortex and are therefore largely acquired or learned movements The degree of loss of movement is permanent. The hand rarely regains any movements other than simple flexion of all the fingers simultaneously and simple movements of flexion and extension at the wrist. The movements of the face and leg are more primitively spontaneous and natural and thus more recovery will take place in them than in those of the arm and hand The extensor (Babinski) plantar response on the paralyzed side, however, remains freely elicitable Hemianesthesia, with or without a crossed homonymous hemianopsia, may accompany the hemiplegia. This occurs only when the posterior limb of the internal capsule is extensively destroyed, the sensory radiations which lie caudal to the pyramidal fibers, and the optic radiations which are placed still further caudally, are affected

There is an upper and a lower motor neuron type of paralysis of ocular movements In paralysis of the upper motor neuron there is a loss of co-ordinated movements. In paralysis of the lower motor neuron there are characteristically present diplopia and squint unless there is complete external ophthalmoplegia The upper motor neuron type of paralysis is a supranuclear paralysis of which there are two varieties. one when the voluntary initiation of conjugate movements is lost, but such movements can still be evoked by reflex stimulation; the other when such movements are totally lost and cannot be elicited In total blindness resulting from bilateral destruction of the visual cortex, the pupillary reactions may remain intact. The lower motor neuron type of ocular paralysis does not occur in hemiplegia

Paraplegia. Paraplegia is a paralysis of the lower part of the body and the legs caused by disease or injury of the upper motor neuron in the spinal cord Both motion and sensation are affected Paraplegia may exist in extension or in flexion.

Common causes of paraplegia are defective development of the spinal cord, infections, injury to the spinal cord, locomotor ataxia, transverse myelitis, chronic alcoholism, malaria, and pernicious anemia

Defective development of the spinal cord, or myelodysplasia with spina bifida, as has been stated in relation to lower motor neuron lesions, usually causes flaccid paralysis and atrophy of the legs. Rarely will a defect in the cervical segments of the cord produce spastic paralyzed legs with knee jerks increased Frequently in the presence of spastic paraplegia there is some atrophy of the muscles of the hands and forearms and, perhaps, loss of pain and temperature sensibility as in syringomyelia.

The diagnosis of these congenital lesions of the pyramidal tract with spastic paralysis is made by physical examination and by the finding of an area of defective cutaneous development overlying defective vertebrae, demonstrated by roentgenologic examination.

In some instances vascular anomalies such as congenital arteriovenous fistulas or venous angiomas may cause sudden spinal paralysis from pressure or rupture. Occlusion of the abdominal aorta at the bifurcation may cause anemia of the cord and sometimes paraplegia.

Pyogenic infections, having produced a pyemia, may originate an infection of the epidural space causing either a granulomatous process with compression of the cord or an extensive purulent process with a rapidiy ascending paralysis which is almost always rapidly fatal The other causes for infectious spastic pa[illegible] may

are accompanied by great excitement and often delirium These movements fulfill the requirements for an extrapyramidal origin arising in the short extrapyramidal neurons in the cortex.

The Cerebellum and Locomotion. The cerebellum functions with the pyramidal system in the maintenance of posture. The harmonious control of the combination of movement and posture is a function of the cerebellum When there is a loss of function of the cerebellum, voluntary movement is grossly disordered and cerebellar ataxia ensues.

Cerebellar Ataxia. Cerebellar ataxia according to Walshe is a disturbance of postural fixation. In acute cerebellar ataxia there are flaccidity and atonicity of the muscles. In chronic cerebellar ataxia there is fixation of the parts while actually in movement as well as of the parts which should be maintaining attitude in the rest of the musculature. The true expression of a cerebellar ataxia is a defect in tone of the muscles. This tonal defect is expressed by abnormalities in the movements of the eyes, of the muscles of articulation, and of the hands, arms and legs.

The ocular movements are manifest on conjugate deviation to the side There is a series of regular horizontal jerks, nystagmus The eyes can move normally laterally. The abnormality is evidenced by inability to sustain the lateral deviation The eyes drift slowly toward the midposition During the slow movement of the eyeballs back to midposition they are suddenly jerked back to the deviated position In unilateral cerebellar abscess and auditory nerve tumors, the nystagmus is slower and its range wider when the eyes are moved toward the side of the lesion than when they are turned away from the side of the lesion

The movements of the muscles of articulation are so affected as to produce scanning speech In scanning speech each syllable is pronounced deliberately and slowly. Movement of the hands reveals an intention tremor, irregular in rate and amplitude and excessive in range

The abnormality of the movement of the hands and arms is easily demonstrated by having the patient touch the index finger tip to the nose The hand and arm commence their course normally but soon an irregular course begins with a to-and-fro jerky movement which increases in width as the finger approaches its destination. The finger finally punches or misses the nose and for an instant continues to wiggle about the end of the nose All movements of the hands are likely to be forceful and to overshoot the mark.

Because of irregular swaying of the body, the gait is irregular and staggering and the maintenance of stance difficult It seems that the arms and legs are not ready to stop on command Sensations are undisturbed The tendon jerks are exaggerated In unilateral lesions the postural disturbances are limited to the side of the lesion

[illegible]

becomes evident in the first two years of life. There is ataxia, with intention tremor of the arms and unsteady gait of cerebellar type. The symptoms remain unchanged throughout life

ACUTE ATAXIA Acute cerebellar ataxia may occur as the only manifestation of encephalomyelitis due to measles, varicella and other acute infectious diseases. Cerebellar ataxia may occur in association with any widespread lesions in the nervous system. Cerebellar abscess is a cause of acute cerebellar ataxia. There are usually present, of course, otitis and mastoiditis, as well as fever, leukocytosis and intracranial hypertension

Cerebellar Deficits. In the syndrome of generalized cerebellar deficit there is [illegible] is im- [illegible] This [illegible] from [illegible]

disease of the motor system are disorders of muscle tone and involuntary movements. Walshe has described these as three main symptom complexes: (1) the syndrome of paralysis agitans (tremor-like rigidity), (2) athetosis and (3) the choreiform syndrome.

Paralysis Agitans (Tremor-like Rigidity). In paralysis agitans according to Walshe there is a uniform muscular hypertonus throughout the entire range of passive or active movement of all muscles except external muscles of the eye. On palpation the muscle has an increased tonus which yields only when an appropriate force is applied On forcefully stretching such a muscle, as on extension at the elbow, there is a jerky relaxation simulating the lowering of a lever by a cogwheel, thus the term cogwheel rigidity This rigidity slows the speed and the range of movement so that facial expresion lessens and finally disappears, giving the patient a masklike rigidity of expression Excessive emotional stimuli are required to break up this rigidity When the patient smiles, the smile moves slowly over the face, and once it has spread, it remains too long In walking, the arms cease to swing and the legs move slowly and in short steps (loss of associated movements). There is a tremor which is a rhythmic movement In mild extrapyramidal involvement the tremor ceases when the patient is at rest, and even in severe instances of involvement it ceases while the patient is asleep Occasionally it may cease while the limb is in active use. During stresses of emotion or in fatigue the tremor increases The tendon jerks are increased, but clonus is absent The plantar response is flexion Occasionally the tremor is entirely absent throughout the course of the illness.

The common form of paralysis agitans or Parkinson's disease affects aging individuals as a part of the manifestations of arteriosclerosis. Less commonly, in its most highly developed form, the disorder is a manifestation of chronic encephalitis, subsequent to an acute encephalitis, a viral disease which occurs sporadically, endemically and epidemically (Von Economo's encephalitis). (See Chapter 15.)

Often the disease begins with aching in the arms, to be followed by tremors of the fingers The tremors may be limited for months to a hand or a foot In due time there is a manifest hypertonia of the muscles more definitely expressed in the flexors than in the extensors As soon as hypertonia is established, the head and body become bent forward, and there is, as well, a slight flexion everywhere in all of the muscles The gait is slow and shuffling and often the patients complain of propulsion or retropulsion The voice is high-pitched, weak and monotonous There is difficulty in beginning to speak, but once started the words are uttered rapidly.

Many and varied are paresthesias and aching pains Disturbances in sweating are common The face is often flushed and expressionless or masklike

The tremor advances, until it finally is slowed after the patient is confined to bed Utter helplessness is often present just prior to death.

Athetosis. The variations in the muscular hypertonus of extrapyramidal lesions seem in some instances to be the cause of slow twisting movements and distorted postures of the arms and legs with fingers hyperextended These movements are aggravated in force and amplitude when movement is performed when the patient is hurried or emotionally tense. No signs of upper motor neuron lesion may be found except in those who have in addition an infantile hemiplegia The movements of the face, tongue and articulation are not affected except in rare forms of bilateral athetosis.

The Choreiform Syndrome. In contrast to the movements of paralysis agitans and athetosis, choreiform movements are associated with diminished muscular tone. These movements are superimposed upon voluntary movements. They are jerky co-ordinate movements of the limbs, trunk and facial muscles The involuntary movements of rheumatic chorea are not associated with extrapyramidal disorders and therefore are described elsewhere in this text (Chapter 18). In severe chorea such as chorea gravidarum, the movements are incessant, of great violence, a

vidual has good vision and is able to see written words but does not understand them, the condition is termed *word blindness* If an individual does not comprehend spoken words there is a *sensory aphasia* If there is only injury to a motor eupraxic center the speech musculature is incapable of forming words, though all other movements in which it functions are normally performed, the condition is *motor aphasia.* When writing movements cannot be made there is *agraphia* A failure to recognize the nature or use of a familiar object such as a spoon is *agnosia.* An individual who has neither paralysis, ataxia of movement, nor sensory loss, yet cannot perform the movements appropriate to the use of a familiar object, has *motor apraxia*

Sensory aphasia consists in an impaired or lost comprehension of the spoken word: expression through speech is disordered It is postulated that the eupraxic center transmits the wrong speech patterns to the motor cortex, and thus wrong words are uttered. These words are often badly arranged, and the patient, being word deaf, is unaware of the mistakes One affected with word deafness cannot carry out spoken orders.

Motor aphasia in its mildest form consists in a loss of memory for the names of familiar objects. In more severe degrees of aphasia the patient is reduced to the utterance of a single word such as "Yes," or perhaps "Yes, yes " (See Diseases of the Larynx, Chapter 4)

In aphasic subjects there is a tendency, when some other movement is asked for, to repeat a movement that already has been carried out to order.

Agnosia and *apraxia* are detected by giving the individual familiar objects and thus determining the capacity to recognize their nature and use. *Motor apraxia* is detected by the presence of an inability to perform familiar but simple movements

THE SENSORY SYSTEM AND LOCOMOTION

All acts of locomotion are initiated by the sensory nervous system. The organs of sense, namely, the eyes, ears, nose, taste buds, touch spots in the skin, and the nerve beginnings in the muscles, bones, joints and viscera, are so constructed as to analyze the environmental energy and select certain kinds of disturbances which are then transformed in the receptor and give rise to nervous impulses These nervous impulses on arrival in the appropriate area in the brain originate visual, auditory, and olfactory sensations, taste, dermal sensation, positional sense of an extremity, or pain Aberrations or false interpretations of these sensations by the brain have been considered in association with the complaint Likewise, since pain is the commonest subject of complaint, the sensory perception of pain was differentiated from the reaction to pain All fibers carrying all of the sensations from the various end-organs in the skin and deeper skeletal tissues arrive at the dorsal root entry zone of the spinal cord Here the modes of sensation are grouped or integrated according to quality. Some impulses probably go no higher than segmented levels of the cord. The impulses for tactile, pressure, postural and vibratory sensibility course up the dorsal columns forming the uncrossed sensory paths ending in the dorsal column nuclei of the medulla Then secondary neurons, carrying the impulses through the decussation to extend upward, traverse the pons and the midbrain and end in the lateral nucleus of the thalamus In the lateral thalamic nucleus all sensations are again integrated, and from this nucleus the third and last neuron carries the remaining impulses which were not integrated in the thalamus to the sensory cerebral cortex and to consciousness

The superficial and deep impulses for painful and thermal sensations on reaching the cord enter the gray matter of the dorsal horn to join a secondary neuron which crosses the cord to reach the lateral column of the opposite side where it turns upward Painful and thermal sensations thus result from nervous impulses that follow crossed sensory paths (spinothalamic tract). Tactile sensibility too has

generalized cerebellar damage The chief differential diagnosis is from the spinal ataxias.

Cerebellar catalepsy and the rare cases of cerebellar fits, tonic in type, often with opisthotonos, are indicative of disease of the subcortical cerebellar nuclei.

In vertigo of cerebellar origin the surrounding objects appear as if rotating toward the side opposite to the lesion. However, this vertigo may be due to affection of the adjacent vestibular nuclei or their connections Likewise the upward and backward and lateral positions of the head are probably due to vestibular disturbances and not to primary cerebellar disease Implication of the vestibular fibers produces vertigo and spontaneous nystagmus laterally and vertically, together with impairment of thermic nystagmus and of other vestibular reactions on the affected side Occipitofrontal headache appears Later a vestibular attitude of the head may develop and there are signs of cerebellar compressions consisting of a reeling gait with a tendency to fall toward the side of the lesion. As the tumor enlarges, other cranial nerve palsies develop A facial nerve palsy is a sign of great localizing value when present

There may be subjective tingling or neuralgic pains in the distribution of the trigeminal nerve. Paralytic changes of the trigeminal nerve are evidenced by decrease or loss of sensation in the trigeminal area and loss of the corneal reflex on the side of the lesion Glossopharyngeal paresis and affection of the upper roots of the vagus produce unilateral palatal palsy on the side of the lesion.

The diagnosis of cerebellar disease is established by the presence of a cerebellar ataxia. If the ataxia is due to a degenerative disease, signs of intracranial hypertension are not present If the ataxia is due to an expanding lesion, such as a tuberculoma or a neoplasm, then papilledema, headache and vomiting are present If the tumor is situated in the posterior fascia of the cranium, there are evidences of involvement of the cranial nerves or there is pressure on the brain stem

In the absence of intracranial hypertension a differential diagnosis includes the possibility of the presence of multiple sclerosis, cerebellar encephalitis from any cause, and also lesions of the contralateral frontal and the contralateral parietal lobes of the hemispheres of the brain.

The Frontal Cortex and Locomotion. The disturbed functions of the frontal cortex which affect locomotion are termed eupraxic. Eupraxia is inexactness of the reproduction of known co-ordinated movements. It is the frontal cortex that stores the patterns for the skilled movements and movement-complexes, particularly of speech and the hand, that are learned during life The eupraxic centers cause the motor cortex to initiate voluntary motor activities when such are desired or necessary. Therefore a loss of function of the frontal cortex with its eupraxic centers causes, not a true paralysis of movement, but an inability to initiate movements at will All movements, however, may still be performed spontaneously when attention is not directed to their performance.

The Speech Function. Speaking and writing, physiologically, are movements; psychologically, they are symbols which express thoughts that refer to things

Disorders of articulation conform to the manifestations of upper and lower motor neuron lesions, the particular manifestation depending on whether the lesion is situated in the afferent (sensory) path, in the motor cortex, or in the efferent (motor) path. In cortical association areas articulated sounds heard, or written words seen, and the sensory impressions left by past speech movements are retained Any lesion cutting off the association areas from the projection areas, or a lesion within them isolating one part from another, will produce a true disorder of speech. The disorder may be sensory (receptive), motor (expressive), or a combination of sensory and motor defects.

If there is only a sensory defect, the hearing of word sounds is normal, but one so affected is unable to understand what is heard and has *word deafness*. If an indi-

The element of light contact or touch is tested by a camel's hair brush or a wisp of cotton touched lightly to the skin, the patient answering immediately on feeling the touch. Symmetric parts should be compared The power of localization is determined by touching the skin with the fingertip and asking the patient to close the eyes and put a finger on the same point. Any error greater than 2 inches is considered abnormal. Localization on the unaffected side should be tested.

For testing the temperature sense, test tubes containing hot and cold water may be used. Touch the surface first with one, then with the other, asking the patient in each case to state whether there is a feeling of hot or cold

A convenient way to test the weight sense is to use two coins differing in weight but preferably of nearly the same size Alternately and synchronously lay them on the extremity or part to be tested, and request the patient to indicate which is heavier. This sense is most acute on the brow, temples, forearm, dorsal surface of hand, and abdomen

The sense of position is tested while the patient's eyes are strictly closed or blindfolded. Taking hold of one of the extremities, flex, extend and move it in a variety of directions, asking the patient to imitate these motions with the corresponding limb of the opposite side, or place one limb in a certain posture and have him describe the position in which it remains

The power of co-ordination depends on the muscular sense, by which is ascertained the amount of strength to be employed, and on the articular and tendinous sense, which informs the sensorium of the position of the various limbs and parts of the body, for instance, the regular and smooth co-operation of individual muscles or muscle groups which are requisite to accomplish a definite action or movement. If these senses are dulled or abolished, the condition of *ataxia* exists However, in ataxia other factors are concerned such as sight and touch.

Ataxia is a disturbance of co-ordination of muscular movements, and is usually of three types. cortical, spinal and cerebellar In *cortical ataxia* the conduction fibers between different centers are usually involved, as in the speech defects of general paresis. In *spinal ataxia* the conducting fibers of deep sensibility are involved In *cerebellar ataxia* the sensory conduction fibers are involved, especially those of the vestibular apparatus In ataxias, eye control and disturbance of the sense of equilibrium and of vestibular control are the most important accompanying factors

Ataxia manifests itself in certain disturbances of station and gait or other voluntary movements. These disorders of co-ordination may be searched for as follows: Ataxia of the upper extremities is tested by having the patient close the eyes and touch, first with one index finger, then with the other, the tip of the nose, the lobe of the ear, the center of the closed eye, or the end of an indicated finger of the opposite hand, or, with the eyes open, to thread a needle, button the coat, or write If these attempts are successful, the co-ordination is good.

Ataxia of the lower extremities may be demonstrated by various methods Have the patient stand, eyes closed, with the heels and toes together. In a perfectly healthy person the swaying of the head will be very slight If ataxia is present, the swaying will be noticeable, and the patient, if not prevented, may even fall. This symptom is called static ataxia or the *Romberg sign* Ask the patient further to walk along a straight line Inability to follow the line signifies motor ataxia In instances of inability to walk, ask the patient, eyes open, to imitate with a foot the movements made by the examiner's hand, for instance, writing in the air, circles, or with eyes closed, to touch with the heel of one foot the knee of the opposite side (knee-heel test).

In all tests for ataxia which are made with the eyes closed, the patient should first rehearse once or twice the required movement with eyes open

In cerebellar and some cortical (frontal) ataxias the patient walks in a reeling, drunken manner, with short steps and feet wide apart. With eyes closed, the patient

a crossed sensory path (ventral spinothalamic tract) as well as traveling upward in uncrossed tracts.

All sensibility is divided into superficial and deep by Walshe, who recognizes four primary modes of superficial or cutaneous sensibility; namely, light touch, cold, warmth and pain. Likewise, deep sensibility is divided into four modes; namely, painless, painful pressure, postural sensibility and vibratory sense.

Each mode of cutaneous sensibility begins in the small groups of special end-organs and is conducted by its own conducting fibers. These special sense organs are at least doubly innervated by the dorsal root fibers so that when sense organs are sufficiently separated in space, two sensory stimuli can be felt and distinctly recognized (Walshe)

EXAMINATION. The superficial and the deep sensibilities may be tested by various means. The *superficial sensibilities* are conveniently tested as follows. (1) light touch, tested by cotton wool; (2) distinction of small differences between the points of a compass; (3) localization the patient indicates spot touched by examiner, (4) recognition of small variations (2 to 5 degrees) in the temperature of objects (a test tube of warm water), (5) pain sense, tested with a needle.

Deep sensibilities usually tested are those of muscular, articular and tendinous senses, as follows: (1) position, tested by imitating with the sound limb the position of the affected limb, by pointing with the sound limb; (2) passive movement: appreciation of movement, recognition of the direction of movements; (3) active movements: imitation of movement by the sound limb, (4) weight sense: (a) with hand supported, recognition of differences in weight; (b) with hand unsupported, comparisons of weight placed in each hand; (5) sensibility of bone, tested by a tuning fork of low pitch over bony areas; (6) joint sensibility, tested by flexing and extending joints, (7) temperature sense, tested by hot and cold test tubes.

These sensory functions are examined in order to determine whether they are abnormally active, absent or perverted In testing the cutaneous and pain senses, the patient's eyes should be kept strictly closed or blindfolded, and instructions given that the patient make prompt response at the instant the artificial stimulus is perceived, using always the same word, "Yes" or "No," but otherwise keeping silent. Promptness of response is important, for slowness in response may indicate a delay in conduction The time elapsing between stimulus and response is, under normal circumstances, one tenth of a second, in disease it may be 10 seconds. In testing tactile, temperature and pain sensibility, the areas in which disturbances are found should be outlined In some instances it is necessary to examine not only the cutaneous surface but also the mucous membrane of the nasal and oral cavities and the external genitalia. The following methods are useful

In order to determine the sensibility to small differences between points on the skin, ordinary compasses with their tips guarded by bits of adhesive plaster, a hairpin, or the heads of two ordinary pins, may be used The patient's eyes being closed, the points are placed on the skin sufficiently wide apart to be recognized as a double contact and gradually brought together until it appears to the subject that he is being touched with a single point only Note also whether one point is felt as two or more; and whether a touch on one side of a limb, or of the body, is felt respectively on the other side of the limb, or on the opposite side of the body The sensibility varies within wide limits. These limits are learned by the examiner through experience

The tip of the tongue is most sensitive; it can differentiate between points 1 mm (about 1/25 inch) apart The finger tips are the next most sensitive areas. In the following order the distance of point differentiation decreases: lips, dorsal surfaces of fingers, tip of nose, forearm, tips of toes, cheeks, eyelids, temples, backs of the hands, neck, leg, dorsa of feet, back, arm and thigh. Over the thigh the patient does well to differentiate points 3 to 4 inches apart

The element of light contact or touch is tested by a camel's hair brush or a wisp of cotton touched lightly to the skin, the patient answering immediately on feeling the touch. Symmetric parts should be compared The power of localization is determined by touching the skin with the fingertip and asking the patient to close the eyes and put a finger on the same point. Any error greater than 2 inches is considered abnormal. Localization on the unaffected side should be tested.

For testing the temperature sense, test tubes containing hot and cold water may be used. Touch the surface first with one, then with the other, asking the patient in each case to state whether there is a feeling of hot or cold

A convenient way to test the weight sense is to use two coins differing in weight but preferably of nearly the same size. Alternately and synchronously lay them on the extremity or part to be tested, and request the patient to indicate which is heavier. This sense is most acute on the brow, temples, forearm, dorsal surface of hand, and abdomen.

The sense of position is tested while the patient's eyes are strictly closed or blindfolded. Taking hold of one of the extremities, flex, extend and move it in a variety of directions, asking the patient to imitate these motions with the corresponding limb of the opposite side; or place one limb in a certain posture and have him describe the position in which it remains

The power of co-ordination depends on the muscular sense, by which is ascertained the amount of strength to be employed, and on the articular and tendinous sense, which informs the sensorium of the position of the various limbs and parts of the body; for instance, the regular and smooth co-operation of individual muscles or muscle groups which are requisite to accomplish a definite action or movement. If these senses are dulled or abolished, the condition of *ataxia* exists However, in ataxia other factors are concerned such as sight and touch

Ataxia is a disturbance of co-ordination of muscular movements, and is usually of three types: cortical, spinal and cerebellar. In *cortical ataxia* the conduction fibers between different centers are usually involved, as in the speech defects of general paresis. In *spinal ataxia* the conducting fibers of deep sensibility are involved In *cerebellar ataxia* the sensory conduction fibers are involved, especially those of the vestibular apparatus In ataxias, eye control and disturbance of the sense of equilibrium and of vestibular control are the most important accompanying factors.

Ataxia manifests itself in certain disturbances of station and gait or other voluntary movements These disorders of co-ordination may be searched for as follows Ataxia of the upper extremities is tested by having the patient close the eyes and touch, first with one index finger, then with the other, the tip of the nose, the lobe of the ear, the center of the closed eye, or the end of an indicated finger of the opposite hand, or, with the eyes open, to thread a needle, button the coat, or write. If these attempts are successful, the co-ordination is good

Ataxia of the lower extremities may be demonstrated by various methods Have the patient stand, eyes closed, with the heels and toes together In a perfectly healthy person the swaying of the head will be very slight If ataxia is present, the swaying will be noticeable, and the patient, if not prevented, may even fall This symptom is called static ataxia or the *Romberg sign*. Ask the patient further to walk along a straight line. Inability to follow the line signifies motor ataxia In instances of inability to walk, ask the patient, eyes open, to imitate with a foot the movements made by the examiner's hand, for instance, writing in the air, circles, or with eyes closed, to touch with the heel of one foot the knee of the opposite side (knee-heel test).

In all tests for ataxia which are made with the eyes closed, the patient should first rehearse once or twice the required movement with eyes open.

In cerebellar and some cortical (frontal) ataxias the patient walks in a reeling, drunken manner, with short steps and feet wide apart With eyes closed, the patient

in walking may reel first to one side or the other, or fall forward or backward. In the frontal, cortical ataxias, which closely resemble cerebellar ataxias, the symptom known as adiadochokinesia (inability to make certain rapid fine movements of the hands, such as five-finger exercises, or rapid wiggling of the toes) is usually absent. In cerebellar ataxias it is more often present

Anesthesia, according to a strict definition, indicates a loss of light touch sensibility, but the term is often employed to denote a loss of any form of sensation. The distribution of tactile anesthesia is somewhat varied. It may be either psychic or due to some organic lesion In general, the most important diseases or conditions which present anesthesia as a symptom are cerebral lesions causing hemiplegia; hysteria and traumatic neuroses, disease of the posterior column, roots, or horns of the spinal cord, especially locomotor ataxia; pressure on the cord (tumor, fracture); neuritis (a frequent cause), and leprosy.

Hemianesthesia is a loss of sensibility confined to one lateral half of the body. When found it is, in the majority of cases, a symptom of hysteria It usually affects the left side, and terminates very exactly at the middle line of the body Not infrequently there is anesthesia of the senses of hearing, taste, smell and sight on the same side The next commonest cause is a lesion of the posterior third of the posterior limb of the internal capsule, at which point the sensory fibers pass upward. Under such circumstances it is usually incomplete and is conjoined with hemiplegia of the same side. Hemianesthesia and hemiplegia on the same side plus oculomotor paralysis of the opposite side (crossed ocular paralysis) are indicative of a lesion in the crus on the same side as the ocular paralysis. Anesthesia of one side of the body with anesthesia of the opposite side of the face (crossed facial anesthesia) may be due to a lesion of the upper portion of the pons. Very rarely hemianesthesia is indicative of a lesion in the optic thalamus, or a large cortical or subcortical lesion of the parietal, temporal, or occipital lobes, or is associated with multiple sclerosis. An incomplete hemianesthesia of one side, with partial hemiplegia of the opposite side, may occur as a result of a unilateral lesion of the spinal cord. Spinal cord lesions cause irregularly distributed disturbances of light touch sensibility, especially important in the early diagnosis of spinal cord tumors

Bilateral anesthesia, sometimes amounting to a double hemianesthesia, but generally confined to the lower extremities and the lower part of the trunk, is rarely, if ever, due to a lesion of the brain It is an infrequent symptom in hysteria. Anesthesia of the lower extremities, if in conjunction with varying degrees of paralysis, is usually due to some lesion affecting the spinal cord such as an injury or compression of the cord by dislocation, fracture, or caries of the vertebrae; spinal menin-

[illegible] xia.
[illegible] uritis
[illegible] alone,

or may occur in multiple and scattered patches in any portion of the body Anesthesia of a single extremity rarely originates from a cerebral lesion, but when arising from this cause, the anesthesia is most marked at the terminal portion of the limb and gradually lessens as the trunk is approached; if caused by a spinal lesion, its proximal border will present a sharp line of demarcation In order to determine whether they are coterminous with the area of distribution of any of the peripheral nerves, the shape and location of isolated areas of anesthesia should be compared with a chart to find if they correspond to definite spinal segments. Single or multiple circumscribed patches of anesthesia are usually due to hysteria, neuritis or tabes dorsalis

An excessive sensibility to tactile and other impressions attends a considerable number of disease conditions and is termed *hyperesthesia*. Areas of hyperesthesia are of *frequent* occurrence in hysteria and constitute the so-called hysterogenic zones, for instance tender points on the thorax, the lower part of the abdomen and the back, pressure on which will excite and, if continued, may stop a hysterical parox-

ysm In neurasthenia there is a frequent hyperesthesia of localized points along the spinal column and on the scalp and thorax The scalp is often tender following headaches (especially of migrainous type) and facial or occipital neuralgias The area supplied by any neuralgic nerve may be temporarily hyperesthetic. The paralyzed side in a hemiplegia may be slightly oversensitive, and in some cases of brain tumor there is a marked and extensive hyperesthesia. In unilateral lesions of the spinal cord there is a narrow zone of hyperesthesia above the level of anesthesia on the side of the lesion

Disturbances of the temperature sense consist in a loss of the cold sense or the heat sense, or both, or a condition of reversal of sensation, cold being called hot and vice versa Such alterations from the normal are especially characteristic of syringomyelia and to a less extent of locomotor ataxia and lesions of the medulla.

Disturbances of the pain sense comprise *hyperalgesia,* an excessive sensibility to painful stimuli, and *analgesia,* a loss of sensibility to pain Analgesia is found particularly in syringomyelia and hysteria

Loss of the muscular, articular and tendinous senses constitutes ordinary, versus cerebellar, ataxia. It indicates an interruption of the sensory conduction tracts for such impressions It is seen especially in lesions involving the incoming sensory fibers, as in locomotor ataxia and Friedreich's disease. Disease in the ascending tracts, myelitic disease, compression, and occasionally lesions at the higher levels of the medulla and pons may cause it. Diffuse lesions, as in multiple sclerosis and paresis, may also be responsible for it.

Of these separate senses, loss of weight sense (muscular anesthesia) may be found alone in hysteria and cortical lesions, impairment of posture sense (articular and tendinous anesthesia) may be present in tabes and neuritis before ataxia is found; static ataxia involves muscular and articular sensation, and motor ataxia concerns articular and tendinous sensations

Astasia-abasia, inability to stand and to walk although the legs are otherwise under control, is generally a symptom of hysteria rather than a separate disease, and most commonly succeeds an emotional storm or an injury. It has been observed also in tabes, multiple sclerosis, spastic paraplegia, multiple neuritis and exophthalmic goiter It has been known to follow infectious diseases, carbon monoxide poisoning, overexertion in walking, and painful affections of the leg There is no paralysis, and while the patient is in bed the movements of the feet and legs show no in-co-ordination, but on attempting to stand or walk the legs give way. Women and young adults are commonly affected

Irregularities of sensation such as allochiria, which is a transference of sensation so that a touch on one side of the body is felt on the opposite side, may be present in hysteria, locomotor ataxia, disseminated sclerosis, and myelitis. Polyesthesia (a touch with one point felt as two) is of the same significance. Delayed conduction (tactile or pain), so that the response may require 10 seconds instead of one-tenth second, may be found, especially of pain, in locomotor ataxia and various peripheral paralyses Of similar moderate suggestiveness are after-sensation, an increasing pain lasting for some minutes after a pin prick, and double sensibility to touch and pain, in which the tactile impression is first perceived, the painful impression coming to consciousness after a varying time

Stereognosis is the power of recognizing the form or shape of objects when handled *Astereognosis* is the loss of this power, and is found in spinal or peripheral lesions attended by complete tactile anesthesia or loss of deep sensibility. In cerebral disease it is significant of a lesion (tumor, hemorrhage) in the parietal lobe, the center for deep sensibility and perception of form

In *paresthesia* the sensations of tingling and numbness may result from lesions of any part of the sensory pathway

In general, lesions of the peripheral nerves commonly affect all modes of sensi-

bility. Localized lesions of the spinal cord may impair some modes while leaving others intact. Thalamic lesions may involve all modes though not always equally. Cortical lesions tend to involve the spatial and discriminatory elements of sensibility.

Spontaneous pain as a result of central lesions characteristically occurs in connection with thalamic lesions. Severe and persisting pain may arise from relatively slight injuries when irritation is set up at the site of injury. Pain as the result of peripheral nerve injury may be of an intense burning quality and may be associated with dryness, redness and extreme hyperesthesia of the skin innervated by the affected nerve (causalgia).

The resulting disability from sensory loss varies and is difficult to evaluate The disability and disorder of movement ensuing on defects in postural sensibility are known as *sensory ataxia* There is an unawareness of the position of the lower limbs and of the range and direction of movements. The benefits of vision in control of these disorders are remarkable, for vision gives direction and, to some extent, control of movement. When the eyes are closed, or when the patient is in the dark, ataxia develops and the patient begins to sway and stagger, a phenomenon familiarly known as Romberg's sign. In the upper limbs, the subject has difficulty in distinguishing by manipulation the size and shape of objects held in the hand, and this is termed *astereognosis* The finger-nose test determines the presence or absence of postural sense in the upper limbs Have the patient endeavor, with eyes closed, to place the index fingertip on the nose. The arm deviates from its normal path, moves around in an uncertain way, and may fail to reach its objective.

In general, with cerebral disease, incontinence of either urine or feces is the result of disturbances of consciousness. The mental apathy associated with frontal lobe lesions often is accompanied by the passage of urine and feces These acts should be termed mental incontinence rather than sphincteral incontinence

In the semicomatose patient a distended bladder often leads to restlessness and indications of distress, and therefore the possibility of its presence is manifest. In acute transverse lesions causing total paraplegia there is retention of urine, followed by overflow, and finally by automatic micturition. The periodic sphincteral relaxation allows the escape of some of the vesical contents but not of all. There is always residual urine. In slowly progressive compression of the spinal cord the initial sphincteral disorder is followed by automatic micturition Acute retention of urine may suddenly develop in one of these bladders. The paralyzed bladder often becomes infected, and chronic infection leads to shrinkage of the organ and to almost continual dribbling of urine, and thus the condition grows worse In total paraplegia from transverse lesions of the cord periodic fecal incontinence occurs.

THE NONSENSORY SYSTEM AND LOCOMOTION

The pathways of the nonsensory stimuli seem to be the two spinocerebellar tracts of the cord These impulses arise in muscles, joints, bones and the labyrinths It is believed that these stimuli are integrated by the gray matter, which includes the red nucleus and [illegible] the cerebellum is the organ the functions [illegible] adjust movements and attitudes for har- [illegible] ut cortical directions.

DEEP SENSIBILITY

Mechanics of Visceral Pain. White states that observations on the pathways of visceral pain in man have revealed that there are sensory nerve endings in the viscera, particularly in the heart and intestine. The afferent axons, similar to those found in cutaneous sensory nerves, run in the autonomic nerves from the thoracic and abdominal organs to the posterior roots of the spinal cord These axons are anatomically and physiologically different from sympathetic and parasympathetic fibers which they accompany in the autonomic nerve trunks. These anatomic differences have

been correlated with knowledge gained from experimental stimulation of human viscera, the results of resection or chemical blocking of the various autonomic ganglia and trunks, and interruption of posterior spinal roots

There are pain-sensitive fibers in the vagus and pelvic parasympathetic nerves, and in the thoracolumbar sympathetic ganglia and splanchnic nerves

In malignant disease of the viscera intractable pain is often due to direct extension of the growth into the spinal nerves (see Autonomic Nervous System, Ch. 23).

Tenderness, which is a painful sensation produced by pressure, is slightly different from hyperalgesia. Hyperalgesia may be present without causing tenderness In some conditions of severe hyperalgesic pain, especially the colics, the patients find application of pressure, even a strong firm pressure, most gratifying. Sometimes there is dissociation between the tenderness of subjective pain and the pain itself, the tenderness being present over the site of the lesion, while the subjective pain may be limited to that region or may be referred to a distant region.

There are three painful reactions to pressure. (1) The pain is increased by pressure of any kind, and the lightest touch causes severe distress (2) The pain is increased by deep pressure only, this generally indicates some deep inflammatory lesion (3) The pain is increased by superficial pressure only. This is usually a manifestation of a psychoneurosis.

Rigidity of the underlying muscles is, as a rule, associated with tenderness and is the only good confirmative sign that pain is present Points which aid in differentiating the malingerer from the actual sufferer are the characteristic changes in respiration and pulse, both in rate and rhythm, that occur when pain is produced Often there are varying amounts of perspiration, especially of the palms of the hands

THE REFLEXES

The reflexes to be tested depend on the prevailing complaints and manifestations Generally and routinely some of the cutaneous or superficial reflexes, the tendinous or deep reflexes and, in certain instances, the organic or excitoreflex action are tested

All reflexes presuppose the traveling of a stimulus from the periphery along the afferent nerve to the motor cells in the cord or medulla The motor cells transform the received stimulus into an impulse which is reflected to the periphery along an efferent (motor) nerve to certain muscles, which in consequence contract involuntarily This reflex action ordinarily occupies from one twelfth to one tenth of a second The superficial or cutaneous reflexes are elicited by irritating the skin or mucous membrane, thus causing contraction of the muscles near the irritated part; the deep or tendon reflexes are produced usually by striking the tendon, but also by sharp percussion of the muscle or the periosteum near the tendon The organic or visceral reflexes involve a definite and co-ordinate response to special stimuli as, for instance, defecation

The Superficial (Cutaneous) Reflexes. The cutaneous reflexes are usually tested by sharply stroking the skin with a pointed object, or by scratching, tickling, pinching and pricking When accurately tested, the cutaneous reflexes are diagnostically important Table 6-1 gives a list of these superficial reflexes

The presence of a cutaneous reflex is of value because it demonstrates that the reflex arc (sensory nerve, spinal segment, motor nerve) on which it depends is normal

Of all the superficial reflexes the plantar reflex is of greatest diagnostic significance. In order to perform the test, the patient must be recumbent and the foot comfortably warm, while the limb should be partially flexed at hip and knee and at the same time rotated outward. The sole should then be gently stroked from the heel toward the toe (Fig 6-67).

In the normal person, in all periods of life after locomotion has been acquired,

bility. Localized lesions of the spinal cord may impair some modes while leaving others intact. Thalamic lesions may involve all modes though not always equally. Cortical lesions tend to involve the spatial and discriminatory elements of sensibility.

Spontaneous pain as a result of central lesions characteristically occurs in connection with thalamic lesions Severe and persisting pain may arise from relatively slight injuries when irritation is set up at the site of injury. Pain as the result of peripheral nerve injury may be of an intense burning quality and may be associated with dryness, redness and extreme hyperesthesia of the skin innervated by the affected nerve (causalgia)

The resulting disability from sensory loss varies and is difficult to evaluate. The disability and disorder of movement ensuing on defects in postural sensibility are known as *sensory ataxia*. There is an unawareness of the position of the lower limbs and of the range and direction of movements. The benefits of vision in control of these disorders are remarkable, for vision gives direction and, to some extent, control of movement When the eyes are closed, or when the patient is in the dark, ataxia develops and the patient begins to sway and stagger, a phenomenon familiarly known as Romberg's sign In the upper limbs, the subject has difficulty in distinguishing by manipulation the size and shape of objects held in the hand, and this is termed astereognosis The finger-nose test determines the presence or absence of postural sense in the upper limbs. Have the patient endeavor, with eyes closed, to place the index fingertip on the nose. The arm deviates from its normal path, moves around in an uncertain way, and may fail to reach its objective

In general, with cerebral disease, incontinence of either urine or feces is the result of disturbances of consciousness. The mental apathy associated with frontal lobe lesions often is accompanied by the passage of urine and feces. These acts should be termed mental incontinence rather than sphincteral incontinence

In the semicomatose patient a distended bladder often leads to restlessness and indications of distress, and therefore the possibility of its presence is manifest. In acute transverse lesions causing total paraplegia there is retention of urine, followed by overflow, and finally by automatic micturition The periodic sphincteral relaxation allows the escape of some of the vesical contents but not of all There is always residual urine In slowly progressive compression of the spinal cord the initial sphincteral disorder is followed by automatic micturition. Acute retention of urine may suddenly develop in one of these bladders. The paralyzed bladder often becomes infected, and chronic infection leads to shrinkage of the organ and to almost continual dribbling of urine, and thus the condition grows worse In total paraplegia from transverse lesions of the cord periodic fecal incontinence occurs

THE NONSENSORY SYSTEM AND LOCOMOTION

The pathways of the nonsensory stimuli seem to be the two spinocerebellar tracts of the cord. These impulses arise in muscles, joints, bones and the labyrinths. It is believed that these stimuli are integrated by the gray matter, which includes the red nucleus and the cerebellum It is therefore conceivable that the cerebellum is the organ the functions of which serve the cerebral motor cortex to adjust movements and attitudes for harmonious co-ordination of motor actions without cortical directions

DEEP SENSIBILITY

Mechanics of Visceral Pain. White states that observations on the pathways of visceral pain in man have revealed that there are sensory nerve endings in the viscera, particularly in the heart and intestine The afferent axons, similar to those found in cutaneous sensory nerves, run in the autonomic nerves from the thoracic and abdominal organs to the posterior roots of the spinal cord. These axons are anatomically and physiologically different from sympathetic and parasympathetic fibers which they accompany in the autonomic nerve trunks. These anatomic differences have

The Deep or Tendon Reflexes. Tendon reflexes are the fundamental response of muscle tone. A tap on the tendon produces a momentary stretch, which in turn stimulates the sensory organs in the fleshy part of the muscle.

A tendon reflex is abolished by an interruption of its reflex arc, either on the afferent or on the efferent side and in total division of the spinal cord The reflex arc may also be interrupted where the afferent and efferent links of the arc meet at the synapse within the spinal cord, for example, as in an injury, a compressing tumor, or syringomyelia. The segmental localization of the reflex arc is made use of in determining the level of a lesion in the cord.

The tendon reflexes are obtained by delivering a quick blow to the tendon with the middle finger of the hand or preferably with a reflex hammer.

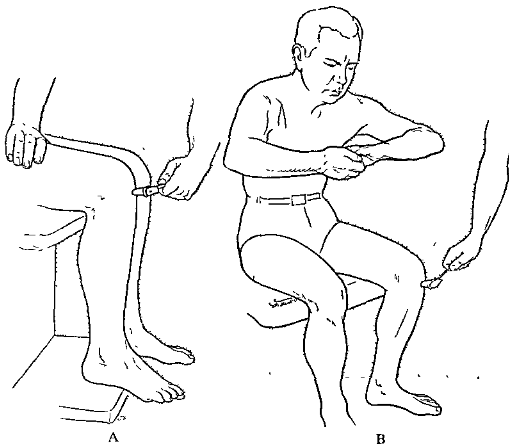

Fig 6 68 A, knee jerk Segmental level L_1, L_2, L_3, L_4 B, re-enforcement to enhance the reaction

In testing *knee jerk* the leg should be at right angles to the thigh (Fig 6-68A). The knees may be crossed, or the examiner may support the leg by placing his hand in the crook of the knee, or push his hand from the outside far enough under to rest it upon the opposite knee of the patient, thus letting the leg swing upon his forearm, or, if the patient cannot sit up, the legs should be slightly flexed and supported. The patient should be directed or diverted so that the leg is relaxed. A sharp blow (with edge of hand, finger, hammer) should be struck upon the tendon just below the patella. Under normal conditions there follows an abrupt jerk of the leg and

Table 6-1. The Superficial Reflexes

Reflex	Method of Eliciting	Response	Segmental Level
Conjunctival	Touch cornea (cotton)	Eyelid closes	Pons
Pharyngeal	Touch wall of pharynx	Pharynx constricts	Medulla
Palatal	Touch soft palate	Palate elevates	Medulla
Scapular	Stroke interscapular region	Scapular muscles contract	C_5 to T_1
Epigastric	Stroke downward from nipple	Epigastrium dimples	T_7 to T_9
Abdominal	Stroke down from costal margin	Abdominal muscles contract	T_{11} to L_2
Cremasteric	Stroke inner side of thigh	Testicle is pulled up	L_1 to L_2
Gluteal	Stroke skin over buttocks	Gluteal muscles contract	L_4 to L_5
Plantar	Stroke sole of foot	Great toe plantar-flexed	L_3 to S_2
Bulbocavernosus	Pinch dorsum of glans penis	Compressor urethrae contracts	S_3 to S_4
Superficial anal	Prick skin of perineum	External sphincter contracts	S_5 and conus

the great toe will be drawn into plantar flexion This reflex depends on continuity between the pyramidal tracts and the spinal reflex. Should the pyramidal tract be interrupted by any cause whatever, the reflex phenomenon is immediately changed, so that instead of plantar flexion there is plantar extension This plantar extension is known as Babinski's sign In infants, who have not yet acquired the skilled act of walking, Babinski's reflex is normally present. The reflexes of Oppenheim, Chaddock, and Gordon are but variations of, or bear the same significance as, the plantar response The segmental level of the plantar reflex is L_3 to S_2

Fig 6-67 Method of obtaining plantar response Segmental level L_3 to S_2

The palatal reflex may be lost in hysteria and bulbar paralysis The superficial reflexes in general may be absent on the affected side in the early stages of hemiplegia

The conjunctival reflex is elicited by touching the cornea with a soft material such as a wisp of cotton. The eyelid closes The reflex has its segmental level in the pons.

When the wall of the pharynx is touched, immediately the pharynx constricts. This reflex has its segmental level in the medulla The soft palate reflex is likewise in the medulla.

The scapular reflex is elicited by stroking the intrascapular region The muscles are seen to contract. The circuit is to C_5, C_6, C_7, C_8, T_1.

The epigastric reflex is obtained by stroking downward from the nipple. There is a quick visible response of the muscles The arc is T_7 to T_9

On stroking downward from the costal margin the abdominal muscles contract The abdominal reflex has its segmental level in T_{11} to L_2. [illegible] below

[illegible] L_2.

[illegible] its

The superficial anal reflex is obtained by pricking the skin of the [illegible] response is contracture of the anal sphincter. Its level is S_5 and below.

... of the calf muscles. Partly extend ... it in the hand seizes the front part of the foot (Fig. 6-70)' and abruptly pushes up or dorsiflexes it upon the leg. The calf muscles contract, forcing the foot downward against the examiner's hand, and if the latter continues to press steadily on the sole of the foot, a rhythmic, clonic movement of the foot will begin and continue. In some cases a very small amount of flexion and pressure will produce it True *ankle clonus must be distinguished* from the few clonic movements, rapidly ceasing, which may be observed as a result of similar manipulations in cases of neurasthenia and hysteria

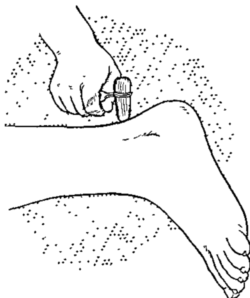

Fig 6-69 Ankle jerk Segmental level S_1, S_2

Paradoxical contraction is sometimes observed while testing for ankle clonus in a leg the muscles of which are extremely spastic It consists of a tonic contraction of the anterior tibial muscles produced by the abrupt dorsiflexion of the foot The segmental level of the ankle clonus is S_1 to S_2

Ankle clonus occurs in those conditions initiating hyperactive knee jerks and ankle jerks. *Often in a patient who has ankle clonus a similar clonus may be produced* by sharply pushing the patella toward the patellar clonus

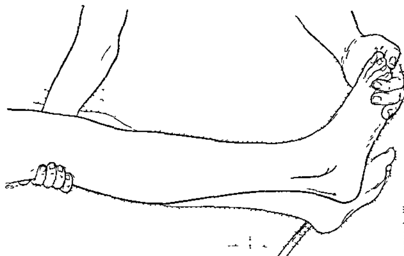

Fig 6-70 Ankle clonus The reflex is obtained while the patient is seated or lying with the knee slightly flexed

There are a few other tendon reflexes which may be used The *jaw reflex* is obtained by tapping the lower jaw directly with the hammer, or the blow may be cushioned as in Figure 6-71. The segmental level of the reflex is the pons. The jaw reflex is often absent in health It is not a significant reflex.

foot If it cannot be obtained, employ re-enforcement; for instance, request the patient to clench his fists strongly; or hooking his fingers together, to pull, one hand against the other, using all his strength (Fig. 6-68B). Either by lessening cerebral inhibition, or by causing an increase of the general muscular tension, re-enforcement may elicit an apparently absent reflex In some cases of exaggerated knee jerk it is possible to obtain a knee clonus equivalent to ankle clonus by fully extending the leg, seizing the patella, quickly pushing it downward and continuing the pressure. As a result the quadriceps may contract rhythmically for a considerable period.

The segmental level of this reflex is L_1 to L_4.

Absence of the knee jerk is caused by a lesion affecting any part of the reflex arc Like the other reflexes, presence of the knee jerk implies a healthy condition of the afferent (sensory) nerve, the posterior roots, the intraspinal paths, and anterior horn of the cord, the efferent (motor) nerve and the muscle itself. If the function of any portion or element of this circuit is in abeyance the reflex is modified Consequently, loss of the knee jerk is a symptom of disease affecting either the motor or sensory fibers or both. Knee jerks are usually absent in neuritis; disease of the posterior roots and columns—locomotor ataxia and Friedreich's disease; diseases of the anterior horns—anterior poliomyelitis (acute or chronic) and Landry's paralysis, and transverse myelitis, if affecting the second and third lumbar segments in which the reflex is localized Knee jerks are absent in apoplexy immediately after the shock, in epilepsy immediately after the convulsion, in injuries to the cord immediately after the accident, and in spinal meningitis. They are frequently lacking in the toxemias of diphtheria, diabetes mellitus (sometimes also insipidus) and chorea.

Exaggeration of the knee jerk shows that the reflex arc is intact, but that either the normal restraining influence of the upper (cerebral) motor neurons is destroyed by lesions affecting the cells, or their fibers which run down in the lateral pyramidal columns are destroyed; or that the irritability of the spinal cord as a reflex center has been increased. Consequently, taking the intracranial causes first, the patellar reflex is exaggerated in the hemiplegia of apoplexy on the affected side shortly, but not immediately, after the attack, in the cerebral paralysis of children, in hereditary cerebellar ataxia; and in general paralysis of the insane The lesions affecting the function of the pyramids are multiple, lateral and amyotrophic lateral scleroses Transverse myelitis, injuries to the spinal cord (after the immediate effects of the traumatism have passed), pressure on the spinal cord, and unilateral lesion of the spinal cord, if situated above the level of the second and third lumbar segments, will, by cutting off the inhibiting cerebral impulses, cause exaggeration of the knee and ankle jerks. If the lesion is unilateral, the exaggerated reflex will be on the same (paralyzed) side. The patellar reflex may also be exaggerated as a symptom of hysteria, neurasthenia, rheumatoid arthritis, tetanus, and strychnine poisoning.

The *ankle jerk* is usually present in health; ankle clonus is usually abnormal. Absence of the ankle jerk has the same, although less important, significance as absent knee jerk, exaggerated ankle jerk and the presence of the ankle clonus are of equivalent value to exaggerated knee jerk, the clonus being found especially in lateral amyotrophic and disseminated sclerosis A brief abortive or false clonus has been mentioned as occurring in neurasthenia and hysteria

In testing *ankle jerk*, extend the patient's leg and hold it up by grasping the foot, at the same time bending the foot upward so as to stretch the tendo achillis.

A better position is obtained by having the patient kneel on a pad or a pillow on a low stool or on the steps of the examining table. When in readiness, strike the tendon sharply and observe the resulting extension of the foot and the contraction of the muscles of the calf of the leg (Fig. 6-69) The segmental level of this reflex is S_1 to S_2.

response of the tendon reflexes in a limb, or between one side and the other, is often of diagnostic import when evaluated by an experienced examiner.

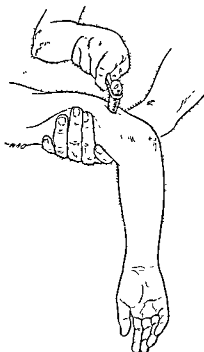

Fig 6-73 Triceps reflex Segmental level C_5, C_6, C_7

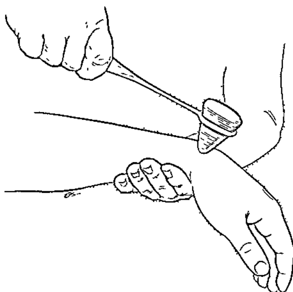

Fig 6-74 Supinator longus reflex Segmental level C_5, C_6

Muscle Tone and the Reflexes. Besides the many disturbances of the nervous system and in the muscles themselves, muscle tone may or may not be changed. If it is increased, it is termed hypertonus, and if it is decreased, there is a hypotonus or an atonia

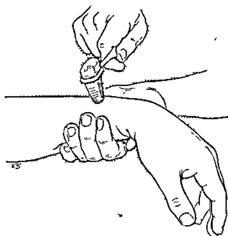

Fig 6-75 Carpometacarpal reflexes Segmental level C_6, C_7, T_1

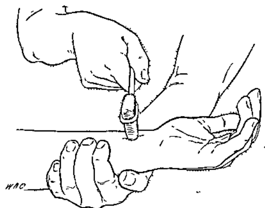

Fig 6-76 Flexor tendon reflex Segmental level C_6, C_7, C_8

A slight but general increase of muscle tone attends preoccupation or emotional states This fact is made use of in the procedure of re-enforcement when there is difficulty in eliciting the tendon jerks

The *scapulohumeral reflex* is obtained by tapping the inferior angle of the scapula. The reflex level is C_5 and C_6. The *supinator longus tendon at the wrist* when tapped by a reflex hammer causes a quick but perceptible contraction of the fingers. The segmental level is C_5 and C_6.

Fig 6-71 Jaw reflex Segmental level, the pons

The deep reflexes of the *upper extremities* are of much less diagnostic value than those of the lower extremities because they are frequently absent in health. The diagnostic significance of these jerks when present, allowing for the difference in localization, is the same as that of the knee jerk

The biceps reflex is obtained by tapping the biceps tendon as illustrated in *Figure 6-72. The reflex level* is C_5 and C_6 The triceps reflex is obtained by tapping the triceps tendon (Fig. 6-73). Its segmental level is C_5, C_6, C_7.

The supinator longus tendon reflex may be obtained by tapping the tendon at the wrist (Fig. 6-74) The segmental level of the reflex is C_5-C_6.

The carpometacarpal reflex is obtained by tapping the back of the wrist. The fingers are extended The segmental level of the reflex is C_6 to T_1 (Fig 6-75)

When the flexor tendons at the wrist are hit with a reflex hammer, the fingers are observed to be transiently flexed. The level of this reflex is C_6, C_7, C_8 (Fig 6-76).

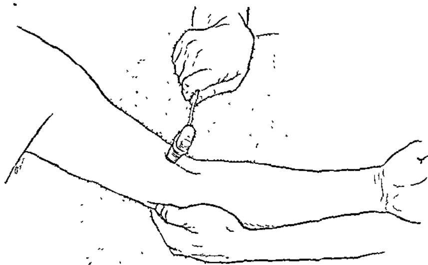

Fig 6-72. Biceps reflex Segmental level C_5, C_6.

The *abolition of a tendon jerk* may be associated with the appearance of an alternative response. This phenomenon is called inversion of the reflex. Inversion may be observed in injuries of the cervical portion of the spinal cord associated with damage to the fifth and sixth cervical vertebrae.

What constitutes a normal degree of briskness in a tendon jerk is judged by the experience of the examiner. The differences between the rapidity or sluggishness of

lesions commonly are found on the thorax, abdomen, neck, shoulders, thighs, buttocks and face. The lesions are unilateral and rarely involve more than three dermatomes. However, extensive eruptions do occur. Within 2 to 3 days after the zoster, a generalized cutaneous eruption resembling varicella may appear. Localized paralysis and atrophy in the muscles of the thorax or abdomen corresponding to the distribution of the eruption may develop These palsies are permanent in most instances. Symptoms of irritation of the parietal peritoneum or pleura or even of the urinary bladder may accompany zoster. Hiccough may occur in association with thoracic zoster.

Frequently some of the cranial nerves are involved by zoster. Affection and paralysis of the third, fourth and sixth nerves are rare. The gasserian ganglion and the first branch of the fifth nerve are frequently affected The eruption affects the upper eyelid, the conjunctiva and cornea and is accompanied by severe pain. The keratitis of zoster may leave permanent scarring of the cornea As the result of anesthesia a neuroparalytic keratitis may ensue. Optic neuritis and loss of vision have been recorded

A facial palsy and zoster of the external auditory canal and loss of taste may be associated The eruption of zoster may occur over the anterior two thirds of the tongue and the hard palate or the anterior pillars of the pharynx.

DIAGNOSIS The eruption of herpes zoster is characteristic The difficulty and the important diagnostic consideration are the differentiation of primary from secondary forms of the disease. The presence of any signs or symptoms which cannot be reconciled with the symptoms of the primary disease arouses a suspicion of some other nervous disease. A zoster may be the first intimation of metastatic malignant disease in or along the spinal column or the sequence of irradiation therapy.

The prognosis of primary zoster is good Herpes zoster of the gasserian ganglion may cause permanent damage to the cornea and in some cases the facial palsy associated with geniculate herpes may persist. The syndrome of crocodile tears may follow herpes of the ear As a sequela of facial nerve zoster there may be profuse lacrimation from the homolateral eye whenever food is taken

Tabes Dorsalis (Locomotor Ataxia) Tabes dorsalis, a manifestation of neurosyphilis, is commoner in men than in women. The disease is manifested from 5 to 20 years after the primary infection by *Treponema pallidum* (see Treponema in Chapter 17) Tabes dorsalis may result from congenital syphilis and may occur in childhood, adolescence or early adult life.

Regularly there is a low-grade inflammation of the posterior spinal ganglia, of the roots between the ganglia, the spinal cord and the meninges. A selective degeneration of the neurons of the posterior columns of the cord is characteristic There may be degeneration of the optic nerve and the nerves supplying the ocular muscles. The trigeminal and the vagus nerves occasionally are affected The nerve pathway which has to do with the pupillary reflex is almost always affected early, producing the Argyll Robertson pupil

SYMPTOMS As seen in the private practice of medicine, patients who have tabes dorsalis usually complain of symptoms which are often not referable to the syphilitic involvement of the spinal cord The disease is often diagnosed from the investigation which follows the discovery of an Argyll Robertson pupil and absence of knee or ankle tendon reflexes

If the patient seeks medical aid for tabes dorsalis, it is often because of disturbances of locomotion or for pain The locomotor disturbances are manifested by disturbances of the sense of position of the parts or losing balance on leaning forward The pain arises from injury by the syphilitic process to the posterior nerve roots and the spinal ganglia which are sensory in function The pain may be mild or severe. If mild, the pain is described in various ways; but generally, if severe, it is described as sharp, boring, shooting, lightning-like, lancinating, compressing

Muscle tone is increased in disease both of the pyramidal and of the extrapyramidal motor systems, but in each case the increase is qualitatively different The spasticity caused by an upper motor lesion is easily to be differentiated from the rigidity of extrapyramidal disease as, for instance, in Parkinson's disease. Both of these types of increased tone are reflex in origin and are abolished if the afferent nerve fiber from the muscle is severed and the reflex arc thus broken Muscle tone is estimated by the manipulation of the limbs to determine the sense of the degree of the active elastic tension in the muscle. The knowledge of the normal range of this tension can be gained only through experience

DISEASES MAINLY AFFECTING THE SENSORY NERVOUS SYSTEM

Herpes Zoster (Shingles, Zona). Herpes zoster is a specific infectious disease caused by the varicella-herpes zoster group of viruses. There are a selective inflammation of the posterior root ganglia and herpetic eruption within the corresponding dermatomes Trauma and diseases and irradiation which involve these ganglia may *cause eruptions of the same type and distribution. There are, therefore, a true* herpes zoster and a symptomatic type of zoster. The vesicles must be regarded as the result of disturbances of function of the ganglia and not as due to the localization of virus in the skin, for the disease cannot be transmitted to experimental animals by inoculation with the vesicular fluid It is thought that zoster is related to chickenpox, *since varicella sometimes develops in persons exposed to zoster and, conversely,* zoster may develop after exposure to varicella.

An attack of zoster confers a high grade of immunity. However, second attacks do occur.

Symptoms This disease occurs sporadically, and it is said to occur occasionally in epidemics in summer and autumn It is a weakly contagious disease It is sometimes possible to trace the infection to a contact.

The incubation period is between 1 and 3 weeks. The first symptom is pain accompanied with severe cutaneous hyperesthesia The pain corresponds *in its distribution* to one or more dermatomes and may be mild or intense There is often a low fever.

The herpes or shingles usually proceed halfway around the body or halfway across the forehead. The lesions are characterized by clusters of vesicles on an *erythematous base which appear in the region of the skin* disturbance of one or more of the posterior spinal nerves The onset of the disease is preceded by or accompanied with neuralgic pain, often very severe, and tenderness in the part. The erythematous patches, more or less oval with the long axis *parallel to the underlying* nerves, occur successively The number of lesions varies from two or three to several dozen Soon the surfaces of the patches are studded with papules which are quickly transformed into vesicles The important feature of the eruption is that it is unilateral. Herpes zoster frequently accompanies or is associated with varicella *However, an attack of varicella does not prevent the patient* from having herpes zoster. In herpes zoster of the forehead, the conjunctiva and the eyeball may be attacked and sometimes the mouth, the tongue or the palate may be affected

After 3 or 4 days erythematous patches appear within the area of *hyperesthesia* [illegible]
Then very [illegible]
spots. The [illegible]
disease is a [illegible]
spinal fluid often contains in excess of 100 lymphocytes per cubic millimeter.

The active phase *of the disease lasts only a short* time, usually a week or less As a rule, the pain persists in middle-aged and aged patients long after the eruption has healed. Hyperesthesia corresponding to the dermatomes involved may persist for years.

Shingles rarely appears on the extremities distal to the elbow or the knee The

any time during the course of the disease. Ocular palsies resulting in ptosis and strabismus and diplopia are common and are characteristically variable in their course However, they may be permanent. The other cranial nerves rarely give symptoms. Occasionally there is deafness. The vagus nerve may be involved, resulting in the so-called posticus paralysis, a bilateral paralysis of the abductors of the vocal cords.

Trophic ulcers, perforating ulcers, especially of the plantar surface of the toes and balls of the feet, are occasionally present. These ulcers are very deep and often penetrate to the bones. Syphilitic clubfeet as the result of involvement of bones and joints of the feet may be present.

Muscular atrophies are rarely encountered. Occasionally a foot drop, due to atrophy of the peroneal group of muscles, and, less frequently, atrophy of the tongue are present. Plantar extension indicates vascular neurosyphilis with involvement of the pyramidal tract, or a supervening general paresis, otherwise it is not present in tabes dorsalis

In the examination for tabes dorsalis, if the disease should be typically manifest, the columnae gracilis and cuneatus (Gall and Burdach) are affected These columns lie between the posterior horns of gray matter and the posterior septum They convey the senses of touch, position (proprioceptive sense) and vibration. However, some of the fibers for touch are in the anterior fasciculi If these posterior columns are affected, there is a flaccidity of the muscles and the joints and a positive *Romberg sign.*

In testing for the Romberg sign, request the patient to stand with the feet close together. If this is accomplished satisfactorily, the examiner stands behind the patient in a position of readiness to catch him if there should be evidence of loss of balance, and the patient is asked to close the eyes If there is more than normal swaying when the eyes are closed, the sign is positive and there is disease of the posterior columns Aside from the normal uncertainty in standing, in labyrinthine and cerebellar disease, the Romberg sign is negative in these disorders

Involvement of the sensory nerve roots by the syphilitic process produces objective and subjective sensory disturbances. The zones of hyperalgesia and hyperesthesia, of radicular distribution corresponding to the level of the nerves affected, are frequently situated in the midthoracic and the lower lumbar regions. There is absence of nerve trunk tenderness In rare instances the cutaneous distribution of the trigeminus nerve is affected, and thus paresthesias are present about the nose and cheeks

The deep sensibility is characteristically affected; the change is manifested by loss of sense of position of various members, for instance, of movements of the toes Early impairment of position and vibratory sensation is always found. This may be slight at first or may affect only the toes, or vibratory sensation may be lost only, over the sacrum In cervical tabes the process begins in the cervical segments so that the disturbance of position sensation and ataxia begin in the upper extremities

The serologic reactions of the blood are positive in from 60 to 75 per cent of those who have tabes The serologic reactions of the spinal fluid generally are positive As there is invariably some degree of meningeal inflammation, there usually is an increase of cells in the spinal fluid, anywhere from 10 to 100 per cubic millimeter This pleocytosis depends on the extent of the meningeal reaction, the acuteness of the process, the stage of the disease and the influence of treatment In quiescent forms of the disease there may be no cells in the spinal fluid, and serologic reactions may be completely negative The globulin content is usually increased The colloidal gold curve is tabetic

DIAGNOSIS An Argyll Robertson pupil is a sign of parenchymatous neurosyphilis, namely, tabes and paresis

In paresis an Argyll Robertson pupil is associated with prominent mental symp-

or squeezing. The attacks of pain are often paroxysmal, come on fairly suddenly, last a few hours, days or weeks, and cease abruptly, only to recur again and again Some patients are free from them, others are tormented by them throughout the course of the disease The distribution of the pain depends on the situation of the syphilitic process If the lumbosacral roots are affected, there are pains in the legs; if the lower cervical roots are involved, the pain is frequently along the ulnar side of the arm, if the lower thoracic roots are affected, the pains are in the abdomen The pain may be localized in the thorax or it may affect the trigeminal roots and simulate neuralgia

As the result of syphilitic injury to the sacral paths, there are complaints of disturbances in the genital, vesical and anal functions. Impotence and loss of libido in men and genital anesthesia in women may occur during the course of the disease. Paresis of the bladder (cord bladder), manifested by retention or incontinence of urine, may be complained of Relaxation of the anal sphincter, which may occur early in the disease, and anal incompetence with loss of feces are grave symptoms

Affections of the joints of trophic origin (Charcot joints) may occur in tabes These joint disturbances may appear after trauma, but because of the absence of pain, the patient is unaware of the seriousness of the injury. A trophic syphilitic joint never improves, the course is progressive. Charcot joints, as the result of destruction of the vertebrae, may permit of serious injury to the spinal cord The symptoms of cord injury are those of a transverse myelitis. Tabetic clubfoot may bring the patient to the physician. Spontaneous fractures of the bones resulting from the presence of gummas are rare.

The impairment of both superficial and deep sensibilities is characteristic of tabes dorsalis. Very early in the course of the disease there may be a feeling in the feet as if they were treading on a soft surface such as a carpet or velvet

During the course of tabes dorsalis there are often feelings of *euphoria*. The family may relate incidents and evidences indicating fallacies of the patient's judgment.

Examination. Ataxia is often present which depends on impairment or abolition of deep position sensation carried by the posterior columns. The ataxia is manifested by a sense of insecurity with uncertainty in walking This uncertainty causes steppage gait, in which each foot is raised higher than in normal gait and then is slapped flatly to the ground A tabetic patient would rather ascend a stairway then descend. There is great difficulty in walking in the dark. There may be bruises of the face or forehead On washing the face, if the patient closes the eyes, a fall forward and injury by striking the forehead against the wall may occur. As the ataxia increases, the tabetic patient walks with the feet farther apart in order to broaden the base of support The uncertainty of the gait is further manifested by the close watch the patient keeps on each step and the use of walking canes Muscular hypotonia is present. It may be so marked as to give hyperextension at the knees (*genu recurvatum*) and flat feet (*flaccid pes planus*).

Very early in tabes the deep reflexes are diminished, and then abolished Loss of knee jerks and ankle jerks is common to all tabetic patients and may even be the first sign and precede the other signs and symptoms by months or years The abdominal reflexes may be hyperactive

The pupillary reflexes are disturbed early. The disturbance may originate in the ciliary ganglion or the pathway between it and the primary visual center, in the centers themselves, in the nuclei of the third nerve or in the sympathetic pathways. The pupils may be miotic, irregular and unequal. They usually do not react to light, but do react during accommodation. This is the Argyll Robertson pupillary action. Once the Argyll Robertson pupil is present, it is permanent.

The ophthalmologist may be the first to announce the presence of tabes dorsalis. The optic nerve is commonly affected. Blindness from optic atrophy

Bilateral lesions produce bilateral anesthesia, and unilateral lesions cause the Brown-Séquard syndrome in which there are analgesia and thermanesthesia on the side opposite to the lesion and loss of proprioceptive sensibility on the side of the lesion If analgesia and thermanesthesia are found over an area corresponding to that of one or more dermatomes, with little or no loss of tactile sensibility, a lesion in the gray matter of the spinal cord is suspected.

Congenital Malformations Involving the Spinal Cord and Meninges. ***Diplomyelia.*** The term diplomyelia refers to doubling or duplication of the spinal cord. The duplication exists in the lower part of the cord and rarely if ever extends above the midthoracic region. There is no constant disturbance of function associated with diplomyelia In approximately half of all cases there is spina bifida of the occult variety. Other abnormalities are common and usually are grossly manifested.

Myelodysplasias. *Myelodysplasia with spina bifida* is a defective development of the spinal cord associated with defect in the overlying vertebral laminas.

In *complete rachischisis* the neural tube lies open and exposed for a number of segments. There is always paralysis.

Meningomyelocele is a rounded surface tumor containing the spinal cord which has retained its connection with the surface ectoderm and is attached firmly to the sac wall.

Meningocele is a bulging surface tumor covered with normal skin Within the skin is a sac composed of the meninges which may or may not be fused so that the sac has a single or a double wall

In *spina bifida occulta* the laminae of the vertebrae are defective. In rare instances the site of the lesion is marked by changes in the overlying skin, such as abnormal growth of hair, a dimple, a deposit of fat or telangiectases. In the majority of these persons there are no symptoms In an occasional individual, when the posterior surface of the spinal cord is attached to the meninges, paralysis is associated In other patients a progressive gliosis may develop and cavities appear in the gray matter, so that the symptoms are similar to those of syringomyelia

There is a malformation of the cervical spine in which the vertebrae are reduced in number and fused into one mass of bone. Spina bifida is usually present This condition is termed *myelodysplasia with Klippel-Feil syndrome*

Myelodysplasia may be associated with *absence of the sacrum and coccyx.* The normal prominences of the buttocks are lost and the intergluteal fold is also absent. Palpation reveals soft tissue where the sacrum should be Roentgenologic examination reveals the defect (Arey)

Myelitis and Abscess of the Spinal Cord. The staphylococci, and streptococci commonly, but occasionally other pyogenic organisms, may reach the spinal cord by way of the blood stream, by penetrating wounds or by direct extension from adjacent foci of infection, and thus originate a myelitis or an abscess.

The onset of the myelitis is often obscured by the presence of symptoms due to the primary infection It usually requires a severe pain in the back and the rapid development of a flaccid paralysis of the legs in order that the symptoms be noticeable or attributable to disease of the spinal cord In some patients the retention of urine is first observed On examination the tendon and the plantar responses are abolished. Sensibility is lost below the level of the lesion. In some instances there has been no serious illness The history reveals that there was a skin infection or trauma with infection which seemingly healed. After this the symptoms of a spinal cord tumor developed

The spinal fluid contains a variable number of leukocytes and lymphocytes depending on the degree of meningeal involvement Protein is almost always increased in the spinal fluid

The diagnosis is made by recognizing a transverse myelitis of rapid onset developing in association with septicemia or with a suppurative process.

toms. Other forms of neurosyphilis usually show a fixed pupil and *are characterized* by signs of disseminated lesions which come on much earlier in the course of syphilis, are much more acute in their onset, and also respond better *to treatment.* The Argyll Robertson pupil in a patient who has a history of primary or secondary syphilis, even in the presence of no other manifest symptoms, is almost diagnostic of tabes. The Argyll Robertson pupil in association with a history of pains in various radicular zones, or a diminished or absent knee jerk or ankle jerk or both, or a history of girdle sensation and vomiting, or the presence of ataxia, or a history of vesical disturbance with impotence, or disturbed position and vibratory sensation in the toes, and hyperesthesia over the nipples, buttocks and ankles, or loss of nerve tenderness, or early optic atrophy—any combination of these—is sufficient to establish a diagnosis of tabes dorsalis. Tabes dorsalis may be diagnosed in the absence of pupillary signs, provided there are signs and symptoms indicative of involvement of posterior roots and posterior columns accompanied with a positive serologic reaction for syphilis These symptoms and signs are pains, crises, loss of deep reflexes, and ataxia The presence of positive or of negative serologic reactions of the blood may influence an error in diagnosis A positive serologic reaction of the blood alone is not diagnostic A positive serologic reaction for syphilis in the spinal fluid is diagnostic if accompanied by appropriate signs and symptoms.

Differentiation of tabes dorsalis may be extensive because of the many possible manifestations of the disease. Some diseases to be differentiated are multiple neuritis (polyneuritis), combined sclerosis of the cord and Adie's syndrome

The etiology and pathogenesis of Adie's syndrome are unknown. The association of this syndrome with other disorders, such as influenza, polyneuritis, encephalitis, multiple sclerosis, orthostatic hypotension, vitamin deficiencies and endocrine disorders, particularly hypothyroidism, has been suggested However, the syndrome seems to be more frequently associated with nervous and emotional disorders. The syndrome is characterized by tonic pupils and sometimes absent tendon reflexes.

A tonic pupil is one having a delayed or slow response to accommodation and convergence. The pupil constricts more than the normal pupil under the same stimulus. It responds slowly to bright light and dilates in the same manner after the stimulus has been withdrawn The tonic pupil is usually unilateral, although it may be bilateral. The abnormal pupil is usually larger than the normal pupil The tonic pupil reacts normally to both atropine and physostigmine. The Argyll Robertson pupils, on the other hand, are usually miotic, bilateral and fixed to light stimulation but react promptly to convergence.

The tendon reflexes most frequently absent in Adie's syndrome are the Achilles and patellar reflexes, although all tendon reflexes may be absent In contrast to tabes dorsalis, the patient with Adie's syndrome has no loss or disturbance of vibratory or position sense, and none of the superficial sensory disturbances, lightning pains or gastric crises.

There are variations in the findings in Adie's syndrome Some patients have tonic pupils alone and others have absence of reflexes alone. In the intermediate positions are those having atypical pupils with absence of one or more tendon reflexes.

DISEASES OF THE SPINAL CORD

In association with the brain and its meninges the spinal cord and its meninges share in a number of infections due to bacteria, viruses, and higher plant and higher animal parasites. Here will be considered some of the diseases which often profoundly affect locomotion, namely, some of the more chronic infections, acute injuries, and metabolic, vascular, unknown and tumorous diseases of the cord and its covering.

Loss of sensibility on one or both sides of the body up to a level corresponding to the lower border of a dermatome indicates that a lesion is in the spinal cord

and impotence are frequent and persistent. There may be ataxia or chronic progressive spasticity.

There may be present pupillary signs, most often fixed both to light and on accommodation Ocular palsies are common If the process be limited to the region about the central canal, there may be a dissociation of pain and temperature sense as in syringomyelia

DIAGNOSIS A history of syphilis, positive serologic reactions in the presence of signs of meningeal reactions and cord changes, an increased number of cells in the spinal fluid, increased globulin and a positive colloidal gold curve are diagnostic of meningomyelitis. The serologic reaction of the spinal fluid may be negative.

The outlook in syphilitic meningomyelitis depends on the duration of the process, on the extent of involvement, and on the treatment. The disease is not cured, but symptomatically the patient may improve under proper treatment

Traumatic Lesions of the Spinal Cord. As the result of trauma the spinal cord may be injured without fracture or dislocation of the spinal column. The history of an injury to the vertebrae signifies the nature of the injury.

The roentgenologic examination will reveal fractured or dislocated vertebrae if they are present. In rare instances, however, no lesions of bone may be demonstrable roentgenologically. The anatomic character and severity of the lesion in the spinal cord frequently cannot be determined at once. If the paralysis is not complete at first, the injury is relatively mild, but if there is complete loss of conduction in the cord, it is impossible to say whether the cord is actually transected or whether there is a transient loss of function without complete anatomic dissolution

A sudden total transection of the spinal cord causes immediately total flaccid paralysis of the limbs, sensory loss, loss of tendon jerks, retention of urine, and sometimes transient absence of all plantar response There is spinal shock If the patient does not die from infected bedsores or cystitis, spinal shock passes off in a few weeks The knee and ankle jerks may return but the plantar response remains extensor. Stroking of the sole may produce involuntary passage of urine

When the lesion is incomplete, the reflexes return after a relatively short time and the muscle tone returns, chiefly in the extensor If signs of compression of the spinal cord develop weeks or months after an injury of the back, the following possibilities should be considered delayed traumatic spondylopathy associated with deformity of the spinal column due to collapse of a vertebra, osteomyelitis, tuberculous spondylitis, and, above all, the extrusion of an intervertebral disk.

Death in the first few hours may occur from paralysis of respiration, from shock or from associated injuries After the first few days the danger is chiefly from infected decubitus ulcers, infections of the urinary tract and pneumonia Lesions high enough to weaken the muscles of respiration cause a high mortality rate

The prognosis as regards recovery depends on the severity of the injury If the lesion is only partial, there is always much functional improvement

Kuhn and Macht have observed the involuntary activity patterns of skeletal muscles innervated below the level of severance in 27 instances of complete section of the spinal cord Some patients survived as long as 42 months The progression of reflex activity following spinal cord transection in this series of patients was. spinal shock, minimal reflex activity, flexor spasms, alternating flexor and extensor spasms and predominant extensor spasms The length of time that different subjects remain in a given stage varies considerably In general, stage 1 lasts for 1 to 6 weeks, stages 2 and 3, 6 weeks to 1 year, stage 4 rarely begins prior to 4 months after injury, and usually is terminated within 1 year, and stage 5 may appear as early as 6 months after the injury and may continue indefinitely Extensor thrust is not common, but can be elicited occasionally in spinal man Spinal standing, similar to that seen in animals with transected cords, can occur in spinal man Sustained patellar and ankle clonus frequently occurs in chronic spinal man Primary extensor

Pyogenic myelitis is almost invariably fatal. However, drainage of such an abscess, by Woltman and Adson, led to recovery.

Pyogenic Infections of the Spinal Epidural Space. Furunculosis caused by staphylococci is the commonest cause of infection of the epidural space. There is fever, as well as severe pain in the back which extends along the course of the spinal nerve roots. Flaccid paraplegia develops in about one week There are rigidity of the spinal column and local tenderness. The spinal fluid contains an excess of cells. Pus may be obtained from the epidural space when lumbar puncture is attempted.

The diagnosis of extradural abscess depends on the rapid development of paraplegia which usually ascends, on the rigidity of the spinal column, on the signs of an acute septic infection and, most important of all, on the discovery of pus in the epidural space.

The prognosis in cases of extradural abscess is very poor Antibiotic therapy is used.

Hemorrhagic Myelitis. Hemorrhagic myelitis is a secondary process due to various bacterial, viral and other poisons Any acute infectious disease may cause a hemorrhagic myelitis, for instance, scarlet fever, diphtheria, rickettsial disease, malaria, pneumonia and septicemia, to mention only a few

The symptoms are those of transverse myelitis, disseminated myelitis, or ascending myelitis with flaccid paralysis The tendon reflexes are lost, the plantar response is extensor, and there is retention of urine The paralysis of some of the muscles is permanent The disturbance of sensibility if present disappears within a short time

The mortality rate is high and averages between 30 and 50 per cent Death generally occurs between the fifteenth and eighteenth days and is associated with coma and bulbar palsy, bronchopneumonia and infection of the urinary tract Some of those who have the disease recover while others sustain a lasting disability

Syphilitic Meningomyelitis. Neurosyphilis produces syndromes which refer to the spinal cord, the brain or the meninges In each of these syndromes there are symptoms which indicate an obvious fact, that the entire nervous system is affected in neurosyphilis.

The changes caused by syphilis may be largely limited to the spinal cord alone or to the spinal meninges, generally it involves both. The infection very often begins in the meninges There are inflammation and fibrous thickening of the meninges and adhesions between the dura and piarachnoid which may contain granulations or gummatous tumors There are endarteritic changes, strangulated thrombosed vessels, and hemorrhage with secondary spinal softening and degeneration The inflammatory process may extend to the roots of the spinal nerves, causing atrophy of the nerve fibers When the syphilitic process affects mainly the spinal cord, there are softening and atrophy In the cord the process may be selective and remain largely restricted to the periphery, limited to certain columns and tracts, or it is partial, or complete at only one level of the cord. In other instances of cord involvement the process is diffuse and disseminated

SYMPTOMS. The meningovascular variety of neurosyphilis commences within the first 5 or 6 years of the infection There may be paraplegia, spinal hemiplegia, quadriplegia, or a Brown-Séquard syndrome. The paralysis is generally spastic but may be flaccid The syndrome may simulate that of subacute poliomyelitis with segmental atrophies and no sensory disturbances

There are often pains in the root zones. These pains are present in the neck, back or loins The pains are often girdle-like and follow definite paths along the arms or legs, and whether mild or severe they are worse at night than in the daytime. Spasms and atrophies of the muscles are present when the motor roots are affected *Meningomyelitis* occasionally is manifested by pains, ataxia and vesical disturbances, and severe headaches are common

EXAMINATION. There is a loss of tendon reflexes. Patchy sensory disturbances, a loss or diminution of sensation below the level of the lesion in the paraplegias, spinal hemiplegias, and quadriplegia are common. Vesical and rectal disturbances

the preservation of the axis cylinder accounts for the possibility of remissions. It is only when both the myelin sheath and the axis cylinder are destroyed that the signs and symptoms become permanent.

SYMPTOMS Multiple sclerosis may be manifested by disturbed functions in one or many different parts of the nervous system For instance, neurologists distinguish a *sacral* form of the disease characterized by sphincteric disturbances of the anus and bladder The *cervical* form of the disease is manifested by acute unilateral ataxia, astereognosis, slight spasticity, and sensory changes. In the *bulbar* form the process is characterized by disturbance in phonation, articulation and deglutition If there are disturbances of function of the facial and trigeminal nerves, the disease is designated as *pontine* multiple sclerosis. Asynergy characterizes a *cerebellar* form of multiple sclerosis. *Cortical* forms of the disease are rare, but when present the manifestations are acute hemiplegia and ophthalmoplegia There are, however, a number of signs and symptoms which occur with sufficient frequency and consistency to make multiple sclerosis a unified clinical disease.

A sufficient number of patients who have multiple sclerosis have scanning speech, tremor and nystagmus so that these constitute a triad of symptoms considered to be diagnostic of the disease. However, these are but a few of the symptoms usually present in the disease

The first symptoms, such as a fleeting ocular palsy manifested by temporary strabismus or a slight visual disturbance, or a mild leakage of urine or a transient weakness of a limb, often signify the onset of multiple sclerosis months or years before the patient is aware that a serious disease is developing

A disturbance of locomotion, manifested by difficulty in walking, often is the first definite symptom. The gait becomes spastic or ataxic and there is increasing hypertonicity of the lower limbs. Often the patient stumbles or falls in walking. The greatest in-co-ordination is often in the upper extremities. Acute ataxia of an arm alone may occur.

In rare instances the onset is acute and is manifested by apoplexy The syndrome is ushered in by hemiplegia, at times accompanied by unconsciousness and, rarely, even by a convulsion In rare instances, too, the illness is that of a transverse myelitis, in these, however, the acute symptoms usually recede.

A slowing, halting, scanning or explosive speech is a common symptom of multiple sclerosis The words are broken up into syllables and scanned, a form of articulation which is, in reality, a dysarthria. Scanning is extremely characteristic.

There may be difficult micturition or slight transitory incontinence Vesical incontinence occurs when there is severe involvement of the sacral segment of the spinal cord Anal incontinence is rarely present

Emotional disturbances such as an impulsive laughter, more rarely crying, often occur early.

EXAMINATION In the early stages of the disease, in the interim between attacks, results of examination may be negative

Coincident with or preceding the development of spasticity, the knee jerks and ankle jerks become hyperactive Plantar extension and clonus are present (Babinski sign). There are early impairment and loss of the abdominal reflexes. Loss of abdominal reflexes accompanied with an ataxic tremor with an intention element are pathognomonic signs of the disease. The tremor comes on gradually, usually in the upper extremities, and frequently becomes extreme. It may become so disturbing as to interfere with dressing and eating. The tremor usually disappears at rest and is absent during sleep

Lateral nystagmus is an early and common sign of multiple sclerosis. It indicates a focus in the medulla or pons

There may be areas of hypalgesia and hypesthesia, or even complete loss of

manifestations in chronic spinal man probably represent the reappearance of primitive and poorly integrated postural activity mediated by the isolated cord, the functional capacity of which seems greater than has been assumed Although spinal man passes through a period in which flexion reflexes alone are active, he may frequently progress to a stage of activity characterized by predominantly extensor reflexes, amounting in many cases to extensor spasm. It is probable that many of the discrepancies between these observations and those of earlier investigators can be explained by the better physical conditions of present-day spinal men.

Circulatory Diseases of the Spinal Cord. The intraspinal blood supply is derived from the central or anterior sulcal branch of the anterior arterial trunk and the peripheral arteries arising from the pial plexuses These two systems, although possessing anastomosis of capillaries, function as end-arteries The arterial distribution is not according to anatomic or physiologic relations The larger vessels pass into the cord and supply the ganglion cells

The veins emerging from the interior of the spinal cord are united into extensive venous plexuses on the surface upon which are situated the main longitudinal channels

Occlusion of the Anterior Spinal Artery. When the anterior spinal artery is occluded, there are sudden paraplegia, absence of defense reactions, dissociated pain and temperature sensory disturbances accompanying disturbances of vesical and intestinal functions. These symptoms vary according to the level involved Flaccid muscle paralysis and segmental atrophy ensue.

Atherosclerosis. Atherosclerotic changes in the blood vessels may be present in the spinal cord, and are most intense in the thoracic part of the cord. Likewise in syphilis the upper thoracic part of the cord will be most affected by syphilitic arteritis

Mild but distinct evidences of degeneration of the posterior column and horn appear in vascular disorders of old age.

In generalized atherosclerosis, signs of defective nutrition of the cord appear under stress or exertion similar to what occurs in the brain Like that of the brain, the anemia of the cord is intermittent in character.

The most frequent symptom is numbness and a feeling of coldness in the lower extremities There is a diminution or loss of vibratory and joint sensibility, and sometimes the sense of touch is impaired There may be local muscular atrophies and spasticity

The effect of atherosclerotic changes in the vessels supplying the peripheral nerves is to decrease the blood supply to the peripheral nerves as well as to the other tissues There results the so-called arteriosclerotic neuritis. The symptoms consist of marked pain, hyperesthesia of the skin, atrophy and glossiness of the skin and occasionally some objective sensory changes and muscular atrophy.

Disseminated (Multiple) Sclerosis. Multiple sclerosis is a chronic intermittent disease of the central nervous system. Remission of a part or all of the symptoms may be short or may last over a period of years. Usually, however, there are repeated relapses with steady aggravation and progression of all signs and symptoms until invalidism and death result.

Multiple sclerosis is essentially a disease of early adult life, in most cases occurring between the ages of 20 and 40 years. The disease is commoner in men than in women

The constant pathologic features of multiple sclerosis consist mainly of numerous and widespread foci of sclerosis of varying ages of duration throughout the central nervous system, degeneration of the myelin sheath and preservation of the axis cylinder in the midst of the foci of sclerosis (periaxial neuritis).

The sclerotic process is situated more in the white matter of the spinal cord, especially the pyramidal tracts, and in the structures of the medulla, pons, midbrain, and the optic chiasm and tract. Owing to the varying ages of the patches of the sclerosis the patient may be observed to have some signs and symptoms which remain permanent and others which are capable of remission

Degeneration of the axis cylinder proceeds until it is finally destroyed The destruction of the myelin sheath alone permits of only a partial impairment of function, while

the preservation of the axis cylinder accounts for the possibility of remissions. It is only when both the myelin sheath and the axis cylinder are destroyed that the signs and symptoms become permanent.

SYMPTOMS. Multiple sclerosis may be manifested by disturbed functions in one or many different parts of the nervous system. For instance, neurologists distinguish a *sacral* form of the disease characterized by sphincteric disturbances of the anus and bladder. The *cervical* form of the disease is manifested by acute unilateral ataxia, astereognosis, slight spasticity, and sensory changes In the *bulbar* form the process is characterized by disturbance in phonation, articulation and deglutition. If there are disturbances of function of the facial and trigeminal nerves, the disease is designated as *pontine* multiple sclerosis. Asynergy characterizes a *cerebellar* form of multiple sclerosis. *Cortical* forms of the disease are rare, but when present the manifestations are acute hemiplegia and ophthalmoplegia There are, however, a number of signs and symptoms which occur with sufficient frequency and consistency to make multiple sclerosis a unified clinical disease.

A sufficient number of patients who have multiple sclerosis have scanning speech, tremor and nystagmus so that these constitute a triad of symptoms considered to be diagnostic of the disease However, these are but a few of the symptoms usually present in the disease.

The first symptoms, such as a fleeting ocular palsy manifested by temporary strabismus or a slight visual disturbance, or a mild leakage of urine or a transient weakness of a limb, often signify the onset of multiple sclerosis months or years before the patient is aware that a serious disease is developing

A disturbance of locomotion, manifested by difficulty in walking, often is the first definite symptom The gait becomes spastic or ataxic and there is increasing hypertonicity of the lower limbs. Often the patient stumbles or falls in walking. The greatest in-co-ordination is often in the upper extremities Acute ataxia of an arm alone may occur

In rare instances the onset is acute and is manifested by apoplexy. The syndrome is ushered in by hemiplegia, at times accompanied by unconsciousness and, rarely, even by a convulsion In rare instances, too, the illness is that of a transverse myelitis; in these, however, the acute symptoms usually recede

A slowing, halting, scanning or explosive speech is a common symptom of multiple sclerosis. The words are broken up into syllables and scanned, a form of articulation which is, in reality, a dysarthria Scanning is extremely characteristic

There may be difficult micturition or slight transitory incontinence Vesical incontinence occurs when there is severe involvement of the sacral segment of the spinal cord. Anal incontinence is rarely present

Emotional disturbances such as an impulsive laughter, more rarely crying, often occur early.

EXAMINATION In the early stages of the disease, in the interim between attacks, results of examination may be negative

Coincident with or preceding the development of spasticity, the knee jerks and ankle jerks become hyperactive Plantar extension and clonus are present (Babinski sign). There are early impairment and loss of the abdominal reflexes. Loss of abdominal reflexes accompanied with an ataxic tremor with an intention element are pathognomonic signs of the disease. The tremor comes on gradually, usually in the upper extremities, and frequently becomes extreme. It may become so disturbing as to interfere with dressing and eating. The tremor usually disappears at rest and is absent during sleep

Lateral nystagmus is an early and common sign of multiple sclerosis. It indicates a focus in the medulla or pons.

There may be areas of hypalgesia and hypesthesia, or even complete loss of

manifestations in chronic spinal man probably represent the reappearance of primitive and poorly integrated postural activity mediated by the isolated cord, the functional capacity of which seems greater than has been assumed. Owing to the varying ages of the patches of the sclerosis the patient may be observed to have some signs and symptoms which remain permanent [illegible] remission

[illegible] er proceeds until it is finally destroyed The destruc[illegible] mits of only a partial impairment of function, while

[illegible]

the preservation of the axis cylinder accounts for the possibility of remissions It is only when both the myelin sheath and the axis cylinder are destroyed that the signs and symptoms become permanent.

SYMPTOMS. Multiple sclerosis may be manifested by disturbed functions in one or many different parts of the nervous system. For instance, neurologists distinguish a *sacral* form of the disease characterized by sphincteric disturbances of the anus and bladder. The *cervical* form of the disease is manifested by acute unilateral ataxia, astereognosis, slight spasticity, and sensory changes. In the *bulbar* form the process is characterized by disturbance in phonation, articulation and deglutition. If there are disturbances of function of the facial and trigeminal nerves, the disease is designated as *pontine* multiple sclerosis Asynergy characterizes a *cerebellar* form of multiple sclerosis. *Cortical* forms of the disease are rare, but when present the manifestations are acute hemiplegia and ophthalmoplegia There are, however, a number of signs and symptoms which occur with sufficient frequency and consistency to make multiple sclerosis a unified clinical disease

A sufficient number of patients who have multiple sclerosis have scanning speech, tremor and nystagmus so that these constitute a triad of symptoms considered to be diagnostic of the disease. However, these are but a few of the symptoms usually present in the disease

The first symptoms, such as a fleeting ocular palsy manifested by temporary strabismus or a slight visual disturbance, or a mild leakage of urine or a transient weakness of a limb, often signify the onset of multiple sclerosis months or years before the patient is aware that a serious disease is developing

A disturbance of locomotion, manifested by difficulty in walking, often is the first definite symptom. The gait becomes spastic or ataxic and there is increasing hypertonicity of the lower limbs. Often the patient stumbles or falls in walking. The greatest in-co-ordination is often in the upper extremities. Acute ataxia of an arm alone may occur

In rare instances the onset is acute and is manifested by apoplexy The syndrome is ushered in by hemiplegia, at times accompanied by unconsciousness and, rarely, even by a convulsion In rare instances, too, the illness is that of a transverse myelitis; in these, however, the acute symptoms usually recede

A slowing, halting, scanning or explosive speech is a common symptom of multiple sclerosis The words are broken up into syllables and scanned, a form of articulation which is, in reality, a dysarthria Scanning is extremely characteristic

There may be difficult micturition or slight transitory incontinence Vesical incontinence occurs when there is severe involvement of the sacral segment of the spinal cord Anal incontinence is rarely present.

Emotional disturbances such as an impulsive laughter, more rarely crying, often occur early

EXAMINATION In the early stages of the disease, in the interim between attacks, results of examination may be negative.

Coincident with or preceding the development of spasticity, the knee jerks and ankle jerks become hyperactive Plantar extension and clonus are present (Babinski sign). There are early impairment and loss of the abdominal reflexes. Loss of abdominal reflexes accompanied with an ataxic tremor with an intention element are pathognomonic signs of the disease. The tremor comes on gradually, usually in the upper extremities, and frequently becomes extreme. It may become so disturbing as to interfere with dressing and eating The tremor usually disappears at rest and is absent during sleep

Lateral nystagmus is an early and common sign of multiple sclerosis. It indicates a focus in the medulla or pons

There may be areas of hypalgesia and hypesthesia, or even complete loss of

sensation. Disturbance of deep sensation, such as position and vibration, are found if the disease affects the posterior columns. Astereognosis may be profound

Ophthalmologic examination often reveals a bitemporal pallor of the optic disks and central scotomas Optic atrophy may produce blindness. However, all of these visual disturbances of the eyes, including total blindness, may show remissions

Ocular palsies with strabismus and double vision occur early or at any time during the course of the disease. Any disturbance of pupillary reactions, however, is not due to multiple sclerosis. Internal ophthalmoplegias are rare in multiple sclerosis

Bulbar and cranial nerve manifestations are rarely present. Occasionally paralysis of the vocal cords, disturbances of phonation, chewing and swallowing, and facial paralysis and deafness may occur

The spinal fluid in multiple sclerosis may show a slight lymphocytosis and a paretic gold curve. The spinal fluid pressure and globulin concentration are within normal limits The serologic reactions are negative

Diagnosis Increased tendon reflexes, spasticity of the lower extremities, plantar extension (Babinski sign), tremor, nystagmus, speech disturbance, ataxia, impulsive laughter, central scotomas, bitemporal pallor and negative serologic reactions in a patient who has had these symptoms remittently for a long time are diagnostic of multiple sclerosis

Combined Sclerosis (Ataxic Paraplegia) Combined sclerosis is a progressive disease of the spinal cord which most frequently results from pernicious anemia The disease may appear in the course of pernicious anemia in the absence of severe anemia It may advance to a paraplegic state

There is degeneration of the posterior and lateral columns of the spinal cord

The disease often commences with paresthesias, which are prominent throughout its course Involvement of the posterior columns gives varying degrees of ataxia of the lower extremities and occasionally of the arms The legs are almost always involved first There is frequently pseudoathetosis of the fingers

The tendon reflexes are often absent and vibration and position sensation are impaired or lost In instances of degeneration of the pyramidal tract there may be hypertonia with increased reflexes and finally a spastic-ataxic paraplegia The sensory disturbances may affect all forms of sensation Incontinence of urine and bedsores attest the severity of the cord involvement late in the course of the disease.

The onset of paresthesias, ataxia, disturbed vibratory and position sensation, diminished deep reflexes, and the presence of plantar extension and paraplegia, accompanied with pernicious anemia are diagnostic Pellagra may give an ataxic paraplegia, but this is a true myelitis

Syringomyelia (Spinal Gliosis). Syringomyelia is thought to be the result of an embryonic defect of development Under normal conditions the primitive glial cells migrate peripherally from the vicinity of the central canal of the spinal cord and differentiate into adult glial cells Probably in syringomyelia spongioblasts fail to migrate and eventually proliferate and thus form dense regions of gliosis in the central portions of the cord which later turn into cavities One or more cavities are present in the region of the cervical enlargement but may be present or extend to any segment of the spinal cord Occasionally the process begins in the lumbosacral enlargement rather than in the cervical region. The cavities from their points of origin in regions of gliosis in the gray matter near the central canal invade the anterior gray matter and the lateral columns or compress these structures

[illegible] the medulla oblongata (syringobulbia) there is a narrow slit-like [illegible] om the fourth ventricle and involving the [illegible] the descending root of the fifth nerve and perhaps the tractus solitarius Median slits are rare.

Men and women past the age of 20 years are affected with equal frequency. It is very rare for more than one instance of the disease to appear in a family.

SYMPTOMS The patient may complain of having burnt a foot or a hand in water too hot for bathing without knowing it until after the burn was sustained. Some muscles or groups of muscles may twitch and may have become weak, shrunken, or perhaps paralyzed The fascicular twitchings of the muscles progress up the arm as the muscles become weak and shrink. If the symptoms of weakness and shrinkage of the arms have been present for some time, paraplegia may have occurred, and the patient is confined to the bed and to the wheel chair.

Pain is not a common symptom in syringomyelia. Occasionally, however, there may be severe localized pains which involve one or both lower extremities. In some the pain is due to the scoliosis and is relieved by supporting the spinal column

EXAMINATION. On examination many and diverse findings are likely to be present which are widely scattered and which may be difficult to classify. The immediately noticeable abnormalities are atrophy and fibrillary twitchings of the affected muscles, deformities of the fingers and hands, and perhaps scoliosis in the thoracic region of the spinal column. The gait is unsteady and station is uncertain. There is paralysis in association with atrophy of the muscles, with loss of reflexes and flaccidity which usually occur first in the hands or arms. Involvement of the intrinsic muscles of the hands causes various deformities of the fingers After the fingers are involved, atrophy affects successively the muscles of the forearm, arm and the shoulder girdle The muscles of the neck, spinal column and thorax become atrophic toward the end of life. Fascicular twitchings in the affected muscles may be present. The muscular atrophy is not symmetric. In advanced instances of the disease there are paraplegia and spasticity of the legs There is a loss of sphincteral control

In some instances changes will be present in the joints of the upper extremities which are identical with the Charcot joints of tabes dorsalis. There are destruction of the cartilage and articular surfaces and relaxation of the capsule and ligaments, so that an abnormal range of movement is possible The bones may also become decalcified, causing spontaneous fractures. Local overgrowth of bones may occur, and the hand may resemble that of acromegaly.

When the lumbosacral part of the spinal cord is the situation of the syrinx, the atrophy and weakness begin in the feet, calves, thighs or hips Irregularities of sphincteral control in these patients are an early symptom

There are changes in the skin and soft tissues. The skin may be dry and thick, or thin and glossy. The thick nails may become opaque and shed Cyanosis, edema and ulcerations may occur on the fingers, causing extensive loss of tissue.

There is a loss of pain sense; tactile sense is not seriously disturbed In some instances all modalities of cutaneous sensibility may be lost in certain regions. The distribution of the anesthesia is variable. It may be bilateral as the result of interruption of the dorsal commissure It may be unilateral as the result of interruption of the posterior horn of gray matter. Sometimes the anesthesia involves the hand or the hand and forearm, presenting the so-called glove or sleeve anesthesia. In most instances the anesthesia is confined to the arms, shoulders, neck and thorax As the process in the cord advances and the posterior columns of the cord are affected, ataxia, loss of proprioceptive sensibility, unsteadiness of station and gait and finally complete anesthesia may develop over the lower half of the body

When the disease involves the cervical enlargements from extension from either side, there are often signs of involvement of the cervical sympathetic nerve, such as Horner's syndrome or unilateral sweating of the face. The descending root of the fifth nerve may be affected, causing analgesia and thermanesthesia of the face

Nystagmus is an indication of invasion of the medulla The tongue becomes atrophied and paralyzed on one or both sides The soft palate and pharynx and the vocal cords are often paralyzed The sixth nerve may be involved When a syrinx from the medulla reaches the cervical segments, there is paralysis of the sterno-

cleidomastoid and trapezii muscles, owing to invasion of the spinal nucleus of the eleventh nerve.

DIAGNOSIS. The diagnosis depends on the presence of a thermo-analgesia, a slowly progressive atrophy of the muscles supplied by the cervical enlargement, accompanied with dissociated anesthesia in the cervical dermatomes, the scoliosis and the trophic changes The presence of a syrinx in the lumbosacral enlargement causes identical signs in the corresponding segments

The differential diagnosis consists of the exclusion of progressive spinal muscular atrophy, leprosy, Raynaud's disease, cervical ribs with compression of the cervical nerve roots, and neurosyphilis.

Syringomyelia is sometimes accompanied by cervical ribs, and if the symptoms happen to be confined to the hand, the diagnosis may be in doubt until the extension of the symptoms is sufficient to make the nature of the process obvious

The disease may progress so slowly that the patient may be active for many years. As a rule, however, syringobulbia pursues a relatively short course. In all instances the prognosis is ultimately grave.

Tumors of the Spinal Cord. Tumors of the spinal cord cause locomotor difficulties by compression of the cord Compression of the cord, aside from that due to trauma, may arise from a decrease in the size of the bony conduit through which the cord passes; for instance, (1) from lesions of the vertebrae, (2) from space-occupying lesions of the meninges or nerve roots and (3) from tumors arising within the substance of the cord itself

In lesions of the spinal cord the attention is directed to the symptoms and the findings which help to determine the segmental level of the lesion and the structures involved in the transverse direction at the level affected When a disease is due to involvement of a neuron system it is designated as a simple systemic disease. When a disease affects more than one neuron system, as in amyotrophic lateral sclerosis, it is designated a combined neuron disease

In degeneration of the intramedullary continuation of the posterior roots of the spinal nerves, as occurs in tabes dorsalis, the cutaneous sensibility and the sensibility of the bones, joints, fascia and muscles are disturbed. Anesthesia for all qualities of sensation or elective losses of one or more sensations may be present The reflexes are lost There is in-co-ordination of movement of the muscles but muscle power is not diminished. The function of the bladder may be impaired or lost

Diseases of the sensory neurons of the cord are distinguished from lesions arising in the peripheral nerves by topography of the sensory disturbance in the peripheral nerve lesions which corresponds to the domain supplied by the peripheral nerve rather than to a distribution corresponding to the domain supplied by a posterior nerve root in a cord lesion

It must be recognized that knowledge alone of the motor, sensory, reflex and visceral representation in the segments of the cord does not permit diagnosis of focal localization or situation of a gross level lesion in the spinal cord Experience is required in order to evaluate and correlate findings with such facts as, for example, that a peripheral motor nerve innervating a given muscle rarely, if ever, arises from a single segment but, through the mediation of plexuses, has its origin in a combination of fibers from the anterior roots of spinal nerves. That is, each muscle has a plurisegmental innervation, and the innervation of muscles of the extremities is by nerve segments at a higher level

Generally extradural sarcomas are most frequent in childhood Intradural meningiomas are commonest among adults. Gliomas of the cord are relatively common Kernohan considers that gliomas of the spinal cord are the same as the cerebral gliomas He describes ependymomas, spongioblastomas, astroblastomas, medulloblastomas and ganglioneuromas. They usually arise in the central gray matter and extend over a number of segments of the cord.

SYMPTOMS. Tumor of the spinal cord commences *with pain, localized and persistent*, associated with cutaneous hyperesthesia at the level of the tumor. The pain is unilateral at first but may become bilateral or girdle in distribution. It is precipitated by coughing, sneezing and lifting If the cauda equina is involved, pain and muscle spasm on flexing the back are severe Often the pain becomes much worse shortly after the patient falls asleep in the reclining position. In children night crying after going to sleep is frequent. In adults pain disturbs or prevents sleep

EXAMINATION The findings on physical examination depend on the stage of development and the situation of the tumor. There may be either spasticity or flaccidity. Flaccid paralysis develops when the anterior surface of the cord is compressed In these lesions an ataxic gait and a positive Romberg sign soon follow. Cutaneous anesthesia below the level of the lesion is not long delayed after loss of proprioceptive sensibility. The anesthesia may begin in the dermatomes just below the level of the lesion and spread down, but more commonly it begins in the lower part of the body and extends slowly upward until it reaches the level of the pain. All modalities of sensibility are affected, but unequally on the two sides of the body. A more severe anesthesia is likely to be on the side opposite the weaker leg.

A lesion situated cephalad to the cervical enlargement of the spinal cord is manifested by muscular hypertonus including the diaphragm and the intercostal muscles Paralysis of respiration may occur. Lesions situated in the cervical enlargement cause paralysis of the arms, thoracic muscles and legs, but not the diaphragm. Lesions situated cephalad to the first thoracic segment may cause Horner's syndrome. The arms and the legs are paralyzed. Tumors of the thoracic segments of the cord cause spasticity and paralysis of the legs Tumors between the thoracic segments of the cord and the lumbosacral enlargement cause spasticity and weakness of the legs. One leg is affected more than the other Only the legs and the sphincters are affected when the lesion is situated in the lumbosacral enlargement.

A tumor of the cauda equina in some patients causes severe pain which extends along the course of the sciatic nerves The pain is increased by flexion or extension of the spinal column, coughing, sneezing, straining and by certain postures The patient may be comfortable when standing but may have intense pain when lying or sitting Loss of control of the bladder develops early The paralysis is flaccid

There are other patients who have a tumor of the cauda who only have pain and spasm of the flexor muscles of the knee, hip and lumbar portion of the spinal column The lumbar lordosis is reduced and the patient walks with the knees semiflexed Anesthesia is present over the buttocks and the posterior surface of the thighs and legs

In all spinal cord tumors pains in the body below the level of the lesion are usually absent Burning, tingling or hot and cold sensations are common. By the time definite anesthesia is present, there is likely to be difficulty in passing urine A loss of sphincteral control is a late symptom of compression of the spinal cord *Loss of control of the bladder occurs before rectal incontinence Toward the end the legs* become spastic and are strongly extended, a state which terminates in paraplegia-in-extension, followed by paraplegia-in-flexion Trophic changes in the skin and decubitus ulcerations may be present

Before any fluid is removed the *intraspinal pressure* is estimated, it normally registers between 12 and 15 cm. of water As soon as the pressure has been estimated, jugular pressure is applied. Sudden rise and rapid fall of the fluid on compression of both internal jugular veins indicate free flow of cerebrospinal fluid within the subarachnoid space Slow rise and fall of fluid or its failure to rise on compression of the jugular veins suggests partial or complete intraspinal block.

Inability to obtain fluid at the fourth lumbar interspace usually signifies that the tip of the needle has failed to enter the subarachnoid space, that fluid is absent or that there is a tumor at this level

cleidomastoid and trapezii muscles, owing to invasion of the spinal nucleus of the eleventh nerve.

DIAGNOSIS. The diagnosis depends on the presence of a thermo-analgesia, a slowly progressive atrophy of the muscles supplied by the cervical enlargement, accompanied with dissociated anesthesia in the cervical dermatomes, the scoliosis and the trophic changes. The presence of a syrinx in the lumbosacral enlargement causes identical signs in the corresponding segments.

The differential diagnosis consists of the exclusion of progressive spinal muscular atrophy, leprosy, Raynaud's disease, cervical ribs with compression of the cervical nerve roots, and neurosyphilis.

Syringomyelia is sometimes accompanied by cervical ribs, and if the symptoms happen to be confined to the hand, the diagnosis may be in doubt until the extension of the symptoms is sufficient to make the nature of the process obvious

The disease may progress so slowly that the patient may be active for many years. As a rule, however, syringobulbia pursues a relatively short course In all instances the prognosis is ultimately grave.

Tumors of the Spinal Cord. Tumors of the spinal cord cause locomotor difficulties by compression of the cord Compression of the cord, aside from that due to trauma, may arise from a decrease in the size of the bony conduit through which the cord passes, for instance, (1) from lesions of the vertebrae, (2) from space-occupying lesions of the meninges or nerve roots and (3) from tumors arising within the substance of the cord itself

In lesions of the spinal cord the attention is directed to the symptoms and the findings which help to determine the segmental level of the lesion and the structures involved in the transverse direction at the level affected When a disease is due to involvement of a neuron system it is designated as a simple systemic disease When a disease affects more than one neuron system, as in amyotrophic lateral sclerosis, it is designated a combined neuron disease.

In degeneration of the intramedullary continuation of the posterior roots of the spinal nerves, as occurs in tabes dorsalis, the cutaneous sensibility and the sensibility of the bones, joints, fascia and muscles are disturbed Anesthesia for all qualities of sensation or elective losses of one or more sensations may be present. The reflexes are lost There is in-co-ordination of movement of the muscles but muscle power is not diminished The function of the bladder may be impaired or lost.

Diseases of the sensory neurons of the cord are distinguished from lesions arising in the peripheral nerves by topography of the sensory disturbance in the peripheral nerve lesions which corresponds to the domain supplied by the peripheral nerve rather than to a distribution corresponding to the domain supplied by a posterior nerve root in a cord lesion

It must be recognized that knowledge alone of the motor, sensory, reflex and visceral representation in the segments of the cord does not permit diagnosis of focal localization or situation of a gross level lesion in the spinal cord. Experience is required in order to evaluate and correlate findings with such facts as, for example,
[illegible] en muscle rarely, if ever, arises from
[illegible] lexuses, has its origin in a combina-
[illegible] nerves That is, each muscle has a
plurisegmental innervation, and the innervation of muscles of the extremities is by nerve segments at a higher level.

Generally extradural sarcomas are most frequent in childhood Intradural menin-[illegible] are commonest among adults Gliomas of the cord are relatively common [illegible] mas
[illegible] nd
[illegible] ber

In consideration of the symptoms of mononeuritis, it is realized that most peripheral nerves are mixed nerves; that is, they contain both sensory and motor fibers. The interruption by disease or section by trauma of a peripheral nerve causes paralysis of the muscles innervated and also sensory loss or changes in the skin innervated by the same nerve. In disease rarely is all of the nerve destroyed; when some parts of the nerve are still intact, there are manifestations of irritative phenomena in addition to aberrations of sensory function Motor irritative phenomena are spasms of the muscle. first small areas of the muscle which are termed fascicular or fibrillar twitchings and later contractures of the paralyzed muscle. In about three weeks atrophy of the flaccidly paralyzed muscle ensues

The sensory irritative phenomena are mainly pain, limited to the distribution of the affected nerve and described as hot, burning, scalding, throbbing or shooting in character. Paresthesia, dysesthesia, causalgia and tenderness along the nerve are common.

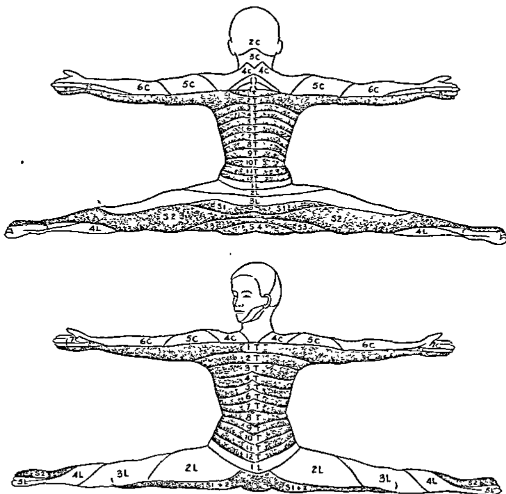

Fig 6-77 Cutaneous distribution of the spinal sensory nerves After Pottenger, F M, Clinical aspects of abdominal pain, J A M A, 102 341 (Feb 3, 1934). Redrawn with permission of the author, who credited Luciani's sketch from Bolk's data, and the publisher.

Neuritis may occur in any one of the spinal nerves. The cutaneous distribution of the spinal nerves is shown in Figure 6-77 Muscular atrophies following injuries of the spinal nerves may be present.

Spinal block, if it results from tumor, frequently causes an increase in the concentration of globulin in the cerebrospinal fluid below the tumor. The fluid may also be xanthochromic. The shade of yellow may vary, and occasionally the fluid above a block is decidedly yellow. The cell count is usually normal, but pleocytosis may occur if the tumor is situated in the spinal canal below the conus medullaris This may help in distinguishing neoplasms from inflammatory lesions

The presence of partial or total subarachnoid block is not pathognomonic of intraspinal tumor, since previous attacks of meningitis, acute myelitis, injuries to the vertebrae or spinal deformities are all capable of interfering with the free flow of cerebrospinal fluid.

Roentgenograms are made of anteroposterior and lateral aspects of the vertebral column, supplemented by stereoscopic and oblique views, localized at the level where a tumor has been suspected In general, roentgenologic evidence of changes resulting from tumors of the spinal cord consists in shadows indicative of erosion of the vertebrae secondary to direct pressure, invasion by the tumor, destruction caused by benign or malignant tumor of the bone, metastatic diseases or hyperostosis.

In addition to the roentgenologic evidence of tumors which is apparent in routine examination of the spinal column, roentgenoscopic and roentgenographic study by the use of radiopaque oil has furnished much additional information in diagnosis and localization of intraspinal tumors. However, radiopaque oil should be used only when tumors are suspected, and the oil should be removed whenever possible.

The manifestations of metastatic lesions may be the same as those of any benign tumor of the spinal cord, except that the progress of a malignant growth is more rapid than that of a benign tumor Metastatic growths from carcinomas of the breast or the prostate gland are most frequent. It must not be forgotten that a primary carcinoma of the breast may have been removed many years before metastasis gives evidence of its presence

Diagnosis If there is demonstrated a level which limits distally the occurrence of both sensory and motor disturbances, a single tumor of the spinal cord is probably present. This lesion may be primary in the cord or secondary to a malignant lesion elsewhere in the body In the presence of such findings there is a history compatible with that of tumor of the spinal cord Special roentgenologic studies should be made by those who are skilled in such procedures, and the roentgenograms should be interpreted by one skilled in such interpretations

When benign or malignant tumors can be removed completely, the outlook is *good, provided the operation is performed early and the cord is not traumatized.* Generally, however, the outlook is unfavorable despite the treatment

DISEASES OF THE PERIPHERAL NERVES

Lesions of the peripheral nerve trunks are common causes of locomotor disability. Each peripheral nerve trunk has motor and sensory components. When the nerve is sectioned, there is a complete loss of both of these functions Partial or progressive lesions which involve these component functions will vary.

There are distinctions to be made in the diseases of the peripheral nerves, the plexuses of nerves, and the nerve roots When disease affects the nerve or the nerve trunk, it is designated as neuritis, the plexus, as plexitis; and the nerve roots, as radiculitis.

Disease of the nerve trunks of the spinal nerves occurs as mononeuritis and polyneuritis The mononeuritis is said to be an interstitial neuritis, whereas the polyneuritis is caused by parenchymatous changes However, several nerves may be affected by mononeuritis The causes for mononeuritis and plexitis occurring in one or several nerves are infections such as leprosy, syphilis, trauma, serum sickness, ... (Reck-

Injury of the Brachial Plexus. The common type of brachial plexus injury is Erb's palsy, which results from strong traction on the shoulder in the delivery of the head in breech delivery, or from drawing of the head and neck away from the shoulders in the effort to deliver the shoulders in cephalic presentations. The paralysis is present immediately after birth

There are adduction and internal rotation at the shoulder, extension at the elbow and often pronation of the forearm and some degree of flexion of the wrist. When the arm is passively abducted, it falls limply. The flexors of the elbow and external rotators of the shoulder are inactive. The grasping reflex is intact In mild injury there is no weakness at the wrist. The biceps and radial reflexes are abolished As a rule it is impossible to demonstrate any loss of sensibility If recovery is delayed, contractures soon develop in the antagonists of the paralytic muscles unless prevented The head of the humerus becomes flattened and the margin of the acromion process becomes depressed in such a way as to prevent complete abduction.

The *distal type* of brachial plexus palsy is less common It involves the intrinsic muscles of the hand with weakness of the long flexors of the wrist and fingers. The grasp reflex is absent There is edema of the hand and there are trophic changes in the nails Loss of sensibility may be demonstrated in the hand. The pupil is smaller than the opposite one and the homolateral eyelid droops, although it can be opened. The iris may remain unpigmented (Fig 6-79).

Complete paralysis of the entire arm and complete loss of sensibility almost up to the shoulder may be present. There is partial arrest of development of the affected arm which is most evident in the hand (Fig 6-78).

Various bone injuries may be associated with brachial plexus palsies such as a fracture of the neck of the scapula, fracture of the clavicle, of the shaft of the humerus or separation of the epiphysis when they are due to postnatal trauma.

Supernumerary cervical ribs may cause abnormal relationships in the neck and lower roots of the brachial plexus. However, supernumerary cervical ribs usually do not give rise to symptoms. The symptoms of root compression may be due to pressure by a first rib when no supernumerary ribs are present. Cervical ribs may be found in several members of a family and have, indeed, been traced through a number of generations (Macklin)

The *symptoms* of root compression rarely arise before the age of 20 years Despite the fact that the ribs are almost always bilateral, the symptoms are almost invariably unilateral Drooping of the shoulders from poor muscular tone, paralysis of the trapezius, or wasting illness may precipitate the symptoms Women are affected three times as often as men. The right arm is more likely to be involved than the left

On *examination*, there is weakness of the hand and forearm with atrophy of the intrinsic muscles of the hand and of the superficial flexors of the wrist and fingers. Paresthesias, numbness and loss of cutaneous sensibility are found over the ulnar half of the hand and inner margin of the forearm The pain and thermal sensibility are reduced without demonstrable loss of tactile sensibility

The radial pulse may be small or absent. In order to test for the presence of circulatory disturbances in a patient who has a cervical rib or ribs, Allen, Barker and Hines recommend that the patient be seated with the arms extended horizontally with the elbows flexed until the forearms are perpendicular to the arms. The head is turned as far as possible away from the side being examined. A positive result of the test is indicated by diminution or disappearance of the radial pulse.

Occasionally the subclavian artery may be spontaneously occluded, resulting in gangrene of the fingers Manifestations resembling those present in syringomyelia or in Raynaud's disease are not uncommonly present in the scalenus anticus syndrome associated with cervical ribs.

Lesions of Peripheral Nerves. Small areas of analgesia surrounded by a larger area of tactile anesthesia suggest lesions of the peripheral nerves. The size and location of the area indicate the nerve or nerves affected. *Traumatic injuries*, either laceration or pressure palsy, are painless. Interstitial neuritis is accompanied by severe pain and by tenderness of the nerve trunks. Incomplete lesions of the peripheral nerves cause such syndromes as *causalgia*. Symmetrically distributed tenderness of the calf muscles and nerve trunks and cutaneous anesthesia or hyperesthesia over the distal parts, which fade out gradually over the more proximal parts, are significant of polyneuritis.

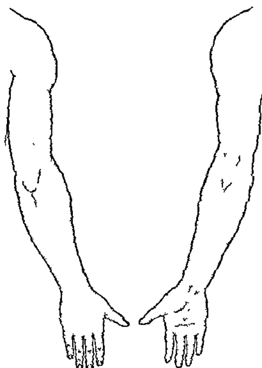

Fig. 6-78. Area of sensory changes in lesions of the brachial plexus (C_5, C_6, C_7, C_8, T_1)

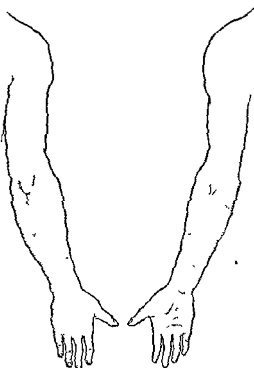

Fig 6-79 Area of sensory changes when the lower part of the brachial plexus is affected (C_8, T_1)

Sensory changes in an area of the skin known to receive its nerve supply from a given nerve corroborate the finding of a weakened or paralyzed muscle, or muscles, innervated by this same nerve. In the diagrams the bordering areas are not depicted. The limits of disturbances of light touch are included in the shaded areas, which merge into the areas where sharp or dull cannot be differentiated

The Brachial Plexus. The brachial plexus, a great nerve plexus of the neck and axilla, is formed by the union of the anterior branches of the lower four cervical nerves and the first thoracic nerve. It supplies the whole upper extremity, and its chief branches are the posterior thoracic, suprascapular, subscapular, internal cutaneous, musculocutaneous, musculospiral, circumflex, median, and ulnar nerves

The muscles supplied by branches of the brachial plexus and methods of testing have been given (pp. 201 and 202). (Nerve supply, C_5, C_6, C_7, C_8 and T_1.)

Sensory Changes in the Skin in Lesions of the Brachial Plexus and Peripheral Nerves of the Arm. In Figure 6-78 are depicted the areas of sensory [illegible] The level of segmental [illegible] ver roots, C_8-T_1, of the brachial plexus are affected, is shown in [illegible]

Fig 6-83 Area of sensory changes of the hand Ulnar nerve distal to origin of its dorsal branch

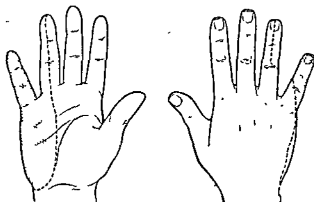

Fig 6-84. Maximal area of sensory changes in skin of the hand *observed in lesions proximal to the origin of the dorsal branch of the* ulnar nerve

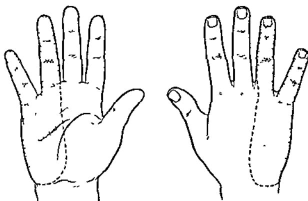

Fig 6-85 Maximal area of sensory changes of hand observed in lesions of the median nerve

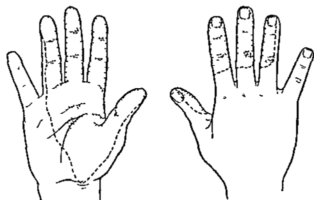

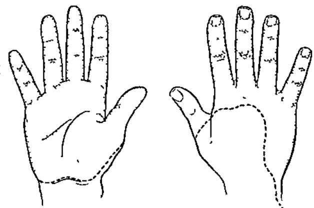

Fig 6-86 Sensory changes in hand when both median and ulnar nerves are affected

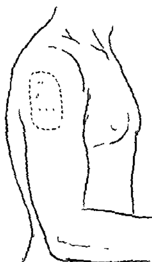

Fig 6-80. Area of sensory changes which attend injuries of the axillary nerve (C_5, C_6)

In *diagnosis* the roentgenographic demonstration cervical ribs in association with slowly developing atro of the muscles of the hand, pain and other disturban of sensation and pulse volume are confirmative.

Sensory Changes in the Skin Resulting From sions of the Peripheral Nerves of the Arm and Ha The area of distribution of sensory change, when *circumflex (axillary) nerve* is injured, is revealed in Fig 6-80. If the lesion involves the axillary nerve too, th will be paralysis of the deltoid muscle.

The *radial nerve* may be injured proximal to its bran the dorsal antibrachial cutaneous nerve. When the ne

brachial cutaneous branch and the musculocutane nerve is injured too, a combined lesion exists. The sens changes in the skin are diagrammed in *Figure 6-82*. T radial nerve also is the *motor nerve* to the brachioradi (C_5 and C_6); extensor carpi radialis supinator (C_5, and C_7); triceps (C_6, C_7); extensor digiti communis; extensor digiti V propri extensor carpi ulnaris; abductor pollicis longus; extensor longus, and exten proprius and extensor pollicis *brevis muscles* (see *Muscle Testing* of the Arm a Hand, pp 213 to 220).

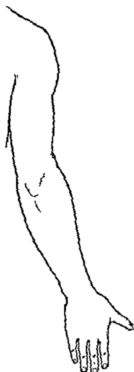

Fig. 6-81 Area of sensory change in injury of the radial nerve proximal to the dorsal antibrachial cutane-

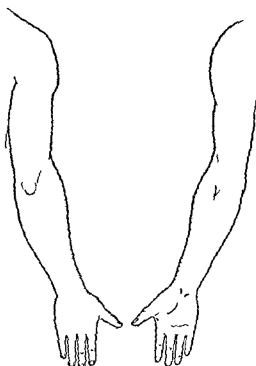

Fig. 6-82. Area of sensory change in injury of the radial nerve distal to the dorsal antibrachial cutaneous nerve

The approximate area within which sensory changes may be present in disturbances of the *posterior cutaneous nerve of the thigh* is revealed in Figure 6-90.

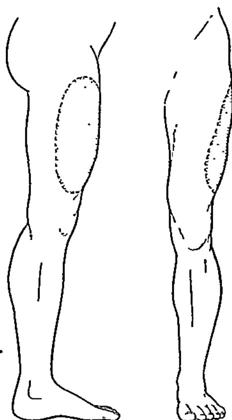

Fig 6-89. Areas of sensory changes in lesions of the lateral femoral cutaneous nerve (L_2, L_3).

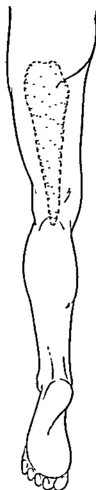

Fig. 6-90. Area of sensory changes in injuries of the posterior cutaneous nerve of the thigh (S_1, S_2, S_3)

The approximate area within which sensory changes may be detected in lesions of the trunk of the *sciatic nerve* is revealed in Figure 6-91.

The area within which sensory changes occur in lesions of both the *sciatic* and the *posterior femoral cutaneous nerve* is revealed in Figure 6-92.

An area within which sensory changes may be revealed in lesions of the *lateral popliteal (peroneal) nerve* above the origin of its musculocutaneous branch is shown in Figure 6-93.

An area within which sensory changes are present in lesions of the *deep peroneal nerve* is shown in Figure 6-94.

Sensory changes in lesions of the *sural nerve* are within the area revealed in Figure 6-95.

The area of sensory changes in lesions of the *medial popliteal or tibial nerves* is revealed in Figure 6-96

The cutaneous changes observed in the skin of the hand or injuries of the ulnar nerve depend on whether the injury is situated distal or proximal to the dorsal branch of the ulnar nerve. When the lesion is situated distal to its dorsal branch, the skin changes are shown in Figure 6-83. When the lesion is situated proximal to its *dorsal* branch, the maximal area of cutaneous changes over the hand ensues (Fig. 6-84).

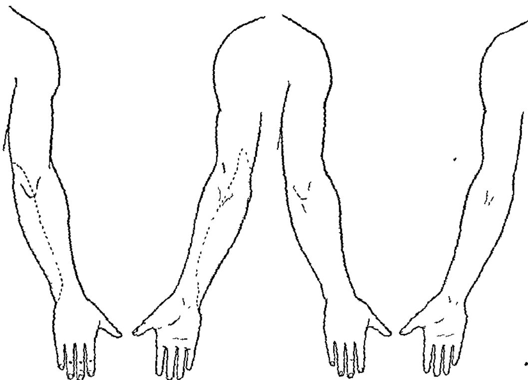

Fig 6-87 Area of sensory changes resulting from injuries of the medial antibrachial cutaneous nerve. Origin, brachial plexus

Fig 6-88 Area of sensory changes resulting from injuries of the lateral antibrachial cutaneous nerve

The ulnar nerve is the motor nerve to the flexor carpi ulnaris, lumbricales III and IV, flexor digitorum profundus, adductor pollicis, flexor digiti brevis V, opponens digiti V, abductor digiti V and interossei muscles of the hand (see Muscle Testing of the Arm and Hand, pp. 213 to 220)

The *median nerve* supplies sensory fibers to the skin of the hand; when maximal injury has been sustained by this nerve, the areas of sensory changes are revealed in Figure 6-85

When both the median and the ulnar nerves are injured, the area of sensory changes over the hand is revealed in Figure 6-86.

The median nerve is the motor nerve to flexor carpi radialis, pronator *teres*, [illegible] s, *flexor* [illegible] *pollicis* [illegible] *d Hand*, pp. 213 to 220).

Injuries of the median cutaneous nerve of the forearm cause sensory changes in [illegible] 6-87 [illegible] earm (a *branch* of [illegible] 6-88.

[illegible] of the Peripheral [illegible] Foot. The area within which sensory changes may *be found*

Allergy. Occasionally polyneuritis develops in association with serum sickness. The muscles supplied by the fifth and sixth cervical roots are usually most severely affected.

Physical Agents. A large variety of poisons may cause polyneuritis Lead neuritis is perhaps the commonest form. Arsenical neuritis was formerly common but has been rare since the medicinal use of arsenic has been discontinued Some of the sulfonamide derivatives may cause severe polyneuritis.

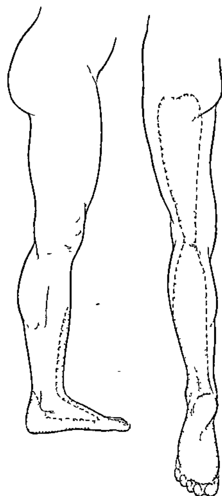

Fig 6-92 Area of sensory changes when the posterior femoral cutaneous nerve and the sciatic nerve are both affected

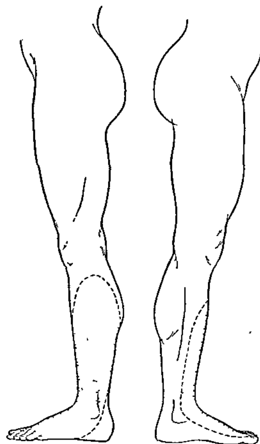

Fig 6-93 Areas of sensory changes in lesions of the common peroneal nerve.

Diabetic neuritis is often clinically latent—that is to say, the patient may not make any complaints, but examination reveals tenderness of calf and plantar muscles and absence of the ankle jerks In more severe diabetic neuritis, pains in the legs reminiscent of the lightning pains of tabes may be complained of, the knee jerks may be lost, and the degree of postural sensory loss may produce an ataxic gait and lead to an erroneous diagnosis of tabes dorsalis

Polyneuritis may be associated with acute *porphyrinuria,* hemochromatosis and amyloidosis

It is thought possible that chronic alcoholism and the cachexia of malignant disease and of chronic tuberculosis may lead to defective absorption of the relevant vitamins This is not substantially proved

Lesions of Spinal Roots. If the spinal roots are injured, the sensory loss corresponds to the distribution of the posterior roots and a radicular anesthesia The area of tactile anesthesia is smaller than that of relative analgesia and there is often so much overlap of the tactile fibers that even in extensive root lesions anesthesia cannot be demonstrated. For instance, in neuritis of the brachial plexus there is usually no anesthesia, but there are usually much pain and tenderness and cutaneous

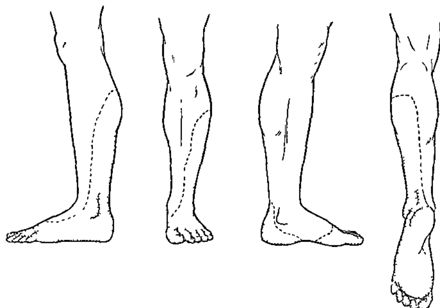

Fig 6-91 Area of sensory changes in lesions of the sciatic nerve (trunk) Origin L_4, L_5, S_1, S_2, S_3

hyperesthesia. Herpes zoster causes relative anesthesia over one or more dermatomes The pain may be relatively widespread, but the anesthesia, if present, is confined to the general region of the cutaneous lesions. The postherpetic neuralgia often causes much suffering in elderly persons See Figure 6-77, page 373

Radiculitis. Radiculitis is defined as an inflammation of the root of a spinal nerve. Usually the greatest part of the inflammation is situated between the spinal cord and the intervertebral canal The spinal cord is somewhat movable in the spinal canal so that when the spinal column is flexed, the cord rises slightly and when it is extended, the cord sinks backward When there is meningitis or radiculitis, flexion of the neck or elevation of a forcefully extended leg causes pain. The Lasègue, Kernig and Brudzinski signs are based on the presence of radiculitis

In radiculitis, as in neuritis, irritative phenomena of the motor nerves occur There are fascicular twitchings which may end in atrophy of the muscles involved if the irritation is progressive or is long-continued

Irritative phenomena of the sensory root are manifested by pain.

Polyneuritis (Multiple Peripheral Neuritis) Multiple peripheral neuritis or polyneuritis is a bilaterally symmetric affection of the peripheral nerve trunks to the limbs which involves both motor and sensory fibers. In some instances cranial nerves may be affected.

Infections. Infections are the commonest cause of polyneuritis In childhood, diphtheria is responsible for a large percentage of all cases It is usually recognized by the [illegible] In the [illegible] ia [illegible]

may also be associated with polyneuritis.

SYMPTOMS. The various etiologic forms of polyneuritis do not differ essentially in their symptomatology. The variation comes in the rapidity of development of the original disease and of recovery from it. Special symptoms which have been described as being peculiar to an etiologic variety of polyneuritis are symptoms of the original disease

The symptoms common to all forms of polyneuritis are the manifestations of a paralysis of lower motor neuron type. The legs are affected earlier and more severely than the arms The muscles below the knee and distal to the elbow are more severely affected than the proximal muscles There is drop foot and in severe instances wristdrop The muscles are tender to pressure In long-standing polyneuritis wasting and contractures and deformities ensue.

EXAMINATION. There are diminution and, later, loss of tendon reflexes All forms of sensibility are impaired, varying in degree and, like the paralysis, maximal over the distal extremities The trunk is rarely involved Early in the severely acute polyneuritis there is tachycardia. In some instances there is cardiac dilatation, and even fatal syncope.

DIAGNOSIS. The diagnosis is made from the findings on examination. If possible, the diagnosis should indicate the etiologic agent.

Acute Febrile Polyneuritis (Landry's Paralysis) Acute febrile polyneuritis differs in no essential from what is described as Landry's paralysis The term Landry's paralysis indicates an acute spreading and often fatal paralysis characterized by the absence of severe or constant changes in the nervous system.

Landry's paralysis and acute febrile polyneuritis commences by a brief period of febrile disturbance with headache, malaise and sleeplessness Often gastrointestinal disorders may precede the appearance of the paralysis The paralysis, which develops rapidly, is of a lower motor neuron type, flaccid, with loss of tendon jerks. Commonly there is paresthesia in toes and feet accompanying the development of paralysis, which spreads up the legs and often involves the arms. The abdominal and back muscles and the facial muscles may be affected The muscles of respiration are less severely weakened than the limb and facial muscles, except in fatal illness.

A pulse rate increase above 110 to 120 is a serious prognostic omen

If the patient does not die, the paralysis begins to diminish, clearing first in the muscles least severely weakened A general debility and exhaustion ensue The tendon reflexes slowly reappear

Interstitial Neuritis or Perineuritis. Interstitial neuritis is a local inflammatory reaction involving chiefly the interstitial connective tissue of the nerve trunk which is distinguishable from the generalized degenerative process of polyneuritis.

There are interstitial neuritides which are associated directly with active foci of infection and others which are not so associated An interstitial neuritis may be directly associated with arthritis, abscesses, lymphadenitis, nasal sinusitis, otitis, cellulitis, erysipelas, tonsillitis, infected teeth and septic ulcers In many instances, when the nerve lies in proximity to the site of infection, the inflammation reaches it by direct lymphatic extension

Debilitating infections such as pneumonia, typhoid fever or influenza may be followed by interstitial neuritis

The mechanism of production of an interstitial neuritis without direct association with foci of infection is not clear

The process commences by inflammation and swelling of the nerve which then becomes dense as the result of proliferation of connective tissue. The axis cylinders are not severely affected

The symptoms begin with deep and superficial pain which follows the course of the nerve trunk and is projected into the region of cutaneous distribution. The pain is sometimes constant but more often intermittent and paroxysmal The disease is extremely chronic

On examination it is observed that movements and postures which serve to place

Nutritional Disorders. It is well known that vitamin deficiency, more especially deficiency of vitamin B, will cause polyneuritis Walshe believes that "Beriberi is probably induced by a toxic product formed in the course of the disordered carbohydrate metabolism that ensues when carbohydrates are consumed in large quantities without the

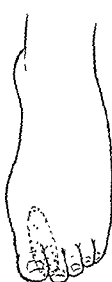

Fig 6-94

Fig 6-94 Area of sensory changes in lesions of the deep peroneal nerve

Fig 6-95

Fig 6-95 Area of sensory change in lesions of the sural nerve

normally occurring natural vitamins with them. Some as yet unknown component of the vitamin B complex is essential to the carbohydrate metabolism of the nerve cell. Despite the clinical evidence at hand, there are yet important gaps in the chain of evidence linking B avitaminosis with the development of polyneuritis"

The role of ethyl alcohol in the etiology of polyneuritis may be associated with lack of vitamin B.

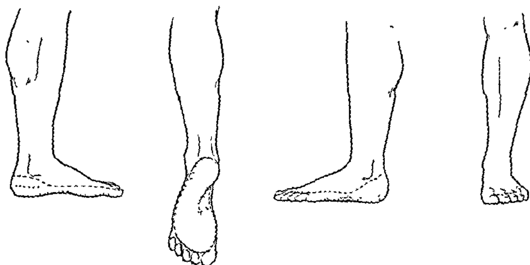

Fig 6-96 Area of sensory changes in lesions of the tibial nerve

Constantly disorders of function in instances of acute polyneuritis precede structural changes since there may be complete or relative absence of visible changes in the nervous system in certain rapidly fatal instances of multiple neuritis such as beriberi and Landry's paralysis. In long-standing, fatal multiple neuritis degenerative changes of wallerian type are found in the axis cylinders of the affected nerves The nerve cells and fibers of the cerebral cortex may also show a degree of degenerative change. The heart shows infiltration with fat and myocardial degeneration.

and is partially anesthetic. The nerve trunk which supplies the region of the lesion begins to become enlarged and palpable Various signs of neuritis slowly develop.

EXAMINATION. On examination the usual findings in leprosy comprise some one or many of the following: The fifth nerve frequently is affected. There may be patches of anesthesia over the forehead, the bridge of the nose and the cheeks which are associated with regions of depigmented skin, and macular, nodular (tuberculoid), or ulcerating nodular cutaneous lesions.

The *maculae* of leprosy involve the corium of the skin, particularly the hair follicles and the sweat glands. The bacillus of leprosy is difficult to demonstrate in these lesions. The *tuberculoid lesions* of leprosy occur as discrete ulcers separated by normal tissue. As the disease advances, these nodules may become continuous masses, pushing other structures aside as they expand With the expansion of the lesions the skin is thinned, and hyperkeratinization with scaling and hypopigmentation, or white spots in the skin, develops

At this stage of the disease the patient loses first the ability to discriminate between heat and cold, next sensibility to pain, and finally, tactile sense.

Frequently the anesthesia is bilateral and sometimes it is symmetric. Neuroparalytic keratitis may ensue All modalities of sensation may be affected but with a certain amount of dissociation. The degree of dissociation of cutaneous sensation, observed in syringomyelia, is not present There is usually palpable thickening of the superficial nerve trunks, especially of the supra-orbital nerve Localized palsies of the facial muscles are common and characteristic The ulnar nerve and the common peroneal nerve are affected early in the course of the disease. Atrophy and weakness appear in the intrinsic muscles of the hands and feet and slowly give rise to various types of flexion deformity including the so-called Simian hand. The ankle jerk and finger reflexes are lost and the knee and biceps reflexes are preserved. The plantar response is abolished and the abdominal reflexes are preserved

Disorders of vasomotor and secretory function and trophic disturbances are constant The hands and feet are cold and blue Sweat secretion is lost and the hair often falls out Dry necrosis of the fingers may be present, but it is commoner to find concentric atrophy of the small bones of the fingers and toes, so that the digit grows smaller and shorter Neuropathic joints are sometimes present The ends of the digits may slough away and leave only stumps of the fingers

The nasal mucous membranes are frequently affected, often with early perforation of the nasal septum. The mucous membranes of the tongue, pharynx and larynx may be involved Involvement of the conjunctiva, cornea and iris which leads to blindness is frequent The liver and spleen frequently are enlarged, and the secondary deposit of amyloid or amyloidosis is exceedingly common in the late stages of this disease Amyloid involving the kidneys gives the symptoms of nephritis

DIAGNOSIS. A definite diagnosis of leprosy must be based on finding of the bacilli in the nasal secretions or in the skin lesions Material aspirated from affected lymph nodes will often reveal the bacilli. For diagnostic purposes, a person who has thickening of the skin around the forehead, eyes, nose and lips, accompanied by other cutaneous lesions, enlargement of lymph nodes in the inguinal and axillary regions, and regions of anesthesia over the extremities or regions of anesthesia with rather severe pain in the arms or legs, has leprosy

The differential diagnosis of leprosy involves the following conditions: cutaneous syphilis, nasal or oral leishmaniasis, yaws and Boeck's sarcoid, Recklinghausen's disease (the form described as forme fruste) and syringomyelia

Nodular leprosy is likely to run a more rapid course than neuritic leprosy and to lead to death within 10 years Neuritic leprosy usually lasts longer Spontaneous remissions are described.

Alcoholic Neuritis. The first symptoms of alcoholic neuritis are cramps and pains in the calf and plantar muscles at night. There may be aching and fatigue in

the affected nerve under tension increase the pain. The nerve trunk is tender, and the tenderness is most severe over the inflamed segments. Sometimes the nerve trunk is palpable. In severe and prolonged instances of the disease there are paralysis and atrophy of the muscles, loss of reflexes and anesthesia

A diagnosis of interstitial neuritis or perineuritis requires history and evidence of a severe or debilitating infection or of neuritis if the tenderness is confined to the nerve trunk and if stretching the nerve causes pain Roentgenographic examinations are of value in excluding diseases of the bones and joints. A conservative prognosis is always given.

Leprosy. Leprosy is due to infection by an acid-fast bacillus, *Bacillus leprae* (*Mycobacterium leprae*), which morphologically resembles the tubercle bacillus.

Regularly in the neural or anesthetic type of leprosy the peripheral nerve trunks have nodular thickenings as a result of proliferation of connective tissue and cellular infiltration. The bacilli are sometimes present in large numbers in the innermost lamellae of the perineurium and in the endoneural septa. The number of bacilli is independent of the degree of tissue reaction In some cases the reaction is relatively acute with active inflammatory reaction and edema, but as a rule the process is chronic and the thickening of the nerve is due chiefly to fibrosis

Degeneration within the posterior roots and of the exogenous fibers of the posterior columns occurs relatively often The posterior root ganglia may be the seat of degeneration and of fibrosis Nonspecific degenerative changes in the brain have been described

In the cutaneous form of leprosy there are firm intradermal and subcutaneous nodules over the face and other exposed surfaces Ulceration and secondary infections are common Mutilation of the parts is due mainly to trauma from lack of sensation and to ulceration secondarily infected In all forms of leprosy lesions usually develop in all organs except the voluntary muscles The cartilage of the nose may be destroyed. The mucous membranes of the mouth, nose and eyes are badly injured. The lymph nodes may enlarge and become granulomatous The testes are often destroyed. Nephritis is common

Distribution Leprosy probably arose in Central Africa It is common in the Balkans, Asia, Asia Minor, India, China, Siberia, Africa, Iceland, Japan, Australia and the Philippines In the United States small numbers of cases are found in the Gulf region, along the Pacific coast and in the Great Lakes region.

Leprosy is common among children whose parents have the disease. If the children are removed from their parents immediately after birth, the incidence of the disease is low Congenital leprosy is rare. Infection is thought to be acquired through the skin or through the nasal mucosa, and to reach the skin by way of the blood stream The incubation period of leprosy is unknown

Two varieties of leprosy, the nodular form and the maculo-anesthetic or neuritic form, are described However, mixed types are common

Symptoms The early symptoms of leprosy may be the same, irrespective of the form of the disease which is about to develop. Irregular fever, sweating, weakness and epistaxis may be present, or a local cutaneous lesion may appear without other symptoms

In the nodular form erythematous lesions develop on the face, forearms, thighs and buttocks which become indurated nodules and eventually ulcerate However, there appear on the skin some spots which are often hyperesthetic at the onset but eventually become anesthetic Nodules appear on the mucosa of the upper part of the respiratory tract, and in the conjunctiva and cornea The ulcerations progress and great mutilations appear, as the result of trauma and secondary infection, and extend These mutilations are the basis for the classic descriptions of the disease.

In the maculo-anesthetic form the cutaneous lesions develop singly rather than in successive outbreaks. In these the macular lesions are white or yellowish and attain 1 to 3 inches (about 2.5 to 8 cm.) in diameter. These depigmented spots appear on the limbs, trunk or face They often have an erythematous border. Often there is neuritic pain at the onset. The skin affected by the macules does not sweat

voluntary control after complete palsy is accompanied by an increased muscle tone After the nerve has regenerated, an asymmetry of the face may remain. This asymmetry is not evidence of incomplete regeneration but evidence that nerve fibers have been misdirected and there thus remains a disturbance of function.

The diagnosis of facial paralysis (Bell's palsy) is usually certain. However, it is well to be aware of the fact that if the palsy has developed slowly, an intracranial neoplasm, especially pontine glioma, is likely

The prognosis is based on the severity of the lesion. Rarely will regeneration fail and the facial muscles atrophy. When regeneration fails, there is extreme relaxation of the tissues, and an unsightly deformity ensues

Guillain-Barré Syndrome *(Polyneuritis With Facial Diplegia). The cause of* the Guillain-Barré syndrome is unknown. An infective agent is not proved

There are no specific pathologic observations. Polyneuritis and degeneration of nerve roots may be found, with occasional changes in the cord.

The syndrome is characterized by symmetric flaccid paralysis with abolition of the tendon reflexes and with subjective sensory symptoms without objective change The patients are afebrile but may have had an antecedent febrile illness. All show a symmetric flaccid paralysis involving particularly the proximal muscles of the limbs and extending in severe forms to the cranial nerves, with a predilection for the seventh nerve Facial paralysis exists but involvement of the other facial nerves is unusual Increase in the protein content of the cerebrospinal fluid occurs frequently but is not a pathognomonic sign Differentiation from poliomyelitis is important and not difficult.

Tumors of Peripheral Nerves. *Neurofibromatosis of Recklinghausen.* The disseminated neurofibromatosis of Recklinghausen is characterized by multiple tumors arising from the sheaths of the spinal or cranial nerves, by cutaneous pigmentation and tumor formation, by abnormalities in the bones and frequently by evidences of defective development and other malformations.

The disease recurs in successive generations of affected families and therefore is believed to be the expression of an abnormal germ plasm The tumors of the nerve trunks are true connective tissue growths When there are intracranial neurofibromas, there may be meningeal growths, usually termed dural endotheliomas Gliomas and areas of gliosis often occur in association with neurofibromatosis of the generalized type In a large percentage of all cases of glioma of the optic chiasm there is associated Recklinghausen's disease. At the age of puberty the tumors become somewhat more numerous and larger than they have been previously The cutaneous lesions are usually symptomless.

Examination reveals irregular areas of yellow or brown pigmentation on the skin Interspersed in the areas between these large spots are small, circular, brownish areas resembling freckles. The skin is often dark. Numerous cutaneous tumors (molluscum fibrosum) of all sizes occur, ranging from 1 mm in diameter to tumors measuring 2 to 3 cm in size These cutaneous tumors are pigmented, soft or firm, and a few are pedunculated

Neurofibromas occur on both the cranial and the spinal nerve roots In some instances they seem to be confined to the two eighth nerves In others, many tumors are found in the cranium The vagus nerve is most frequently affected, and the fifth nerve stands next in frequency At times the brain stem and cerebellum are compressed by large neurofibromas

Tumors occurring on the spinal nerve roots give rise to signs of compression of the spinal cord or cauda equina They cannot be recognized as neurofibroma before operation even though cutaneous tumors are present It is unusual to find intracranial growths in the presence of pronounced cutaneous lesions

Plexiform neuromas extending diffusely through the tissues may occur over the cranium, causing elephantiasis of the scalp Plexiform neuroma may occur in the eyelid, orbit, sella, in the bones of the skull and in the arm or leg.

those muscles during activity. Tingling and numbness in the feet and toes are often present. These symptoms may or may not be associated with other indications of chronic alcoholism, for instance, looseness of the bowels, morning nausea, loss of appetite, tremor of the hands and rapidity of the pulse and flushed cheeks Gradually weakness of the legs and subjective sensory symptoms become more prominent and an altered mental state (polyneuritic psychosis or Korsakoff's psychosis) ensues. The memory is so bad that the names even of familiar objects are forgotten; there may be disorientation as to place and time. The patient may indulge freely in fictitious reminiscences.

Examination in the initial stage reveals marked tenderness to pressure of the plantar and calf muscles. The knee jerks may still be present but the ankle jerks are absent. There is cutaneous hyperesthesia, a moderate degree of sensory impairment (pain, touch, temperature, vibration) and postural modes of sensibility over the feet and toes Sensory loss spreads up the limbs and impairs postural sensibility so that the ambulant patient is likely to be ataxic and to sway when in the Romberg position.

In the advanced stages of the disease there is great loss of power in the distal segments of the limbs Often there is drop foot manifested by a high-stepping gait, but less often wristdrop. Paralysis progresses and complete invalidism may ensue. The muscles shorten, and contractures and deformities develop. The cutaneous hyperesthesia may make all handling of the limbs painful and difficult

Arsenical neuritis very closely resembles alcoholic neuritis even in the occasional presence of the polyneuritic psychosis This disease is exceedingly rare since the decrease in the employment of arsenical therapy

Neuritis of the Facial Nerve (Bell's Palsy) Bell's palsy follows an infectious interstitial neuritis or it results from exposure to cold There is a hemorrhagic interstitial neuritis involving that part of the nerve which lies in the temporal bone in close relation to the middle ear

In Bell's palsy resulting from interstitial neuritis there is pain, localized usually in the ear, extending into the cheek or into the occiput In Bell's palsy resulting from chilling, the palsy precedes the pain

Variations in symptomatology depend on the site of the lesion. If the lesion is distal to the point at which the chorda tympani separates from the seventh nerve, taste is not affected Involvement of the geniculate ganglion is accompanied by a herpetic eruption within the concha and external auditory canal. If the lesion is situated between the geniculate ganglion and the brain stem, there is no overflow of tears and the eye remains dry The presence of any one of these symptoms forces the assumption to be made that the lesion is probably situated inside the cranium and is not a simple Bell's palsy

On examination there is a hypotonicity of some and paralysis of other muscles of the face on the side of the paralyzed nerve The forehead and the cheek are smooth. The corner of the mouth sags The forehead cannot be wrinkled, the eye closed or the corner of the mouth retracted The patient cannot whistle Labial enunciation is affected. There is always an accumulation of food outside of the teeth on the affected side. Taste is lost over the anterior portions of the tongue. The lower lid falls away from the bulbar conjunctiva and tears run down the cheek, for the lacrimal punctum is no longer in position to collect them. Blinking of the eyelid is associated with twitching of the mouth

When the palsy is complete, the affected side of the face sags and the lip and cheek often become edematous. As a rule, the pain ceases within a few days

Within a few weeks examination reveals some return of muscle tone and later there is power of movement. The recovery is prompt and complete if the palsy is partial If paralysis has been complete, return of power is slow. The return of

A benign neurofibroma rarely undergoes sarcomatous degeneration and metastasis.

The presence of cutaneous lesions or multiple subcutaneous nodules offers, as a rule, no difficulty in diagnosis since their nature is evident. In the central type of the disease the diagnosis cannot be made before operation. Roentgenograms of the bones may be helpful in diagnosis.

There is a *forme fruste of Recklinghausen's disease* characterized by the pigmented skin lesions without tumors

It is unusual to see a patient who is seriously disabled by this condition Intracranial or intraspinal tumors are serious since they are almost always so numerous that they cannot be removed.

DISEASES OF THE ANORECTAL REGIONS AND GENITALIA

THE ANORECTAL REGIONS

THE PELVIC OUTLET

The topographic markings of the structures which limit the area within which the anus, rectum and the external genitalia are situated are known as the pelvic outlet The pelvic outlet is bounded anteriorly by the pubis, and laterally by the descending rami of the pubis and the ascending rami of the ischia. Posteriorly is the coccyx, and near its lateral limits are the spines of the ischia The greater and the lesser sacrosciatic ligaments form a diamond-shaped space which is divided into two triangles The anterior one is the urogenital and the posterior one is the anal triangle (Fig 7-1) These triangles may be visualized by passing an imaginary line

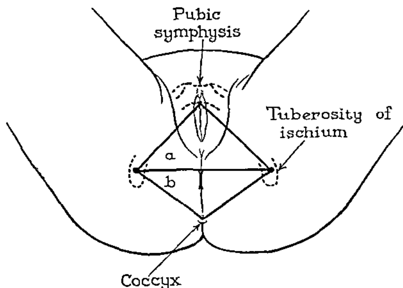

Fig 7-1 Pelvic outlet a, urogenital triangle. b, anal triangle

from the anterior portion of one ischial tuberosity to the opposite one Such a line passes about ½ inch (1 27 cm) anterior to the anus. This imaginary line passes through the dorsal portion of the central point of the perineum At the central point of the perineum the anteroposterior and transverse muscles meet. This point is sometimes designated the perineal body

THE PERINEUM

The Perineal Fascia and Muscles It is clinically important to remember that there are several layers of perineal fascia and muscles which may have implications in perineal infections and injuries. The first layer of the superficial fascia is continuous with the

some

on the perineum anterior or lateral to the anal verge and the cyst often does not contain hair.

Unless complicated by infection, the condition is symptomless, although at times there may be slight discharge. Infection in due time is the rule. The symptoms then are those of superficial pain due to abscess, swelling, tenderness and fever In many cases there is a history of numerous acute episodes and surgical operations. Often relief follows simple incision.

A skin-lined orifice, or orifices, oval or round, situated in the midline over the sacrococcygeal region are usually indicative of pilonidal cyst or pilonidal disease. Such openings often, but not always, are hair-containing. In pilonidal cyst or sinus a probe passed through the orifice passes upward, whereas in a fistula-in-ano the probe will pass downward These sinuses and cysts tend to recur even after careful attempts have been made to remove them surgically

Hidradenitis Suppurativa. Hidradenitis suppurativa is a chronic inflammatory disease of the skin and subcutaneous tissue in those regions in which the apocrine sweat glands are situated; namely, the axillary, mammary, inguinal, genital and perianal regions This condition may resemble, according to Jackman, pilonidal disease.

The diagnosis of perianal manifestations of hidradenitis suppurativa is usually not difficult if the examiner thinks of this disease when he encounters what appears to be extensive anal fistula or pilonidal disease with many sinuses. Examination with the patient under anesthesia may be necessary to distinguish pilonidal cysts or anal fistula from hidradenitis suppurativa

Dermoids and Teratomas. Dermoids and teratomas are often midline tumors *attached to the periosteum of the sacrum and lying between the sacrum and the* rectum. The presence of the tumor often is not suspected until the size of the mass gives symptoms of pressure or unless the tumor is discovered on routine examination The tumor may burst into the rectum, and the patient may give a history of expelling a tuft of hair and teeth Occasionally a tooth or a tuft of hair may be visualized on protoscopic examination The diagnosis can be established by biopsy if teeth or hair is not present

THE ANUS AND RECTUM

The anal canal extends from the rectum to the anus or its opening on the skin, a distance of 1 to 1½ inches (2 5 to 3 8 cm.) It begins at the level of the levator ani muscles and ends at the apex of the prostate gland, which is directly in front of it, and with the tip of the coccyx behind and a little above. With the body vertical the anal canal has its axis inclining upward and forward toward the bladder, as soon as the sphincter ani is passed, the axis of the rectum changes to upward and backward toward the hollow of the sacrum. In introducing a speculum it should always be inclined first anteriorly and then posteriorly Opposite the level of the levator ani the circular muscular fibers increase to form the internal sphincter This extends down the anal canal for a distance of approximately 1 inch (2 5 cm) and ends above the skin margin The external sphincter surrounds the lower part of the canal and stretches in a spindle shape from the tip of the coccyx to the central point or tendon of the perineum Anteriorly it blends with the fibers of the levator ani and the other muscles of the perineum It is a thick, powerful, voluntary muscle and extends outward to the mucocutaneous junction.

Mucous Membrane The upper half of the mucous membrane of the anal canal has six or eight longitudinal ridges or folds (*columns of Morgagni*). Between the lower ends of these columns are small hollows called the crypts (of Morgagni), and the free edges

the anal canal The superior and inferior valves spring from the left posterior quadrant a short distance above and below the middle valve. At the juncture of the rectum and

surrounding parts and the dartos muscle The second layer of the *superficial fascia* (Colles' fascia), a fibrous underlayer, is continuous with the scrotum and passes forward to form the subcutaneous (Buck's) fascia of the penis, covers the spermatic cord, and is continuous with the deep layer of the superficial fascia of the abdomen (Scarpa's fascia). The anterior layer of the triangular ligament blends with the posterior layer of the deep superficial fascia. The deep layer of the triangular fascia is a continuation downward of the pelvic fascia, the obturator fascia, and passes onto the levator ani muscles and closes the gap between these muscles.

The superficial perineal space is situated between the crura of the penis covered by the ischiocavernosus muscles

The deep perineal space lies between the layers of the triangular ligament and contains the compressor urethrae muscle embedded in which is Cowper's gland with its duct which empties into the bulbous urethra

Extravasations of urine or blood in moderate amounts occur from injuries to the *penis anterior to the triangular ligament and thus pass into the superficial space and* are confined there Since this space extends forward and is continuous over the scrotum, the extravasating fluid passes forward and distends the scrotum In greater extravasations the urine may extend to the penis and along the spermatic cord, over the crest of the pubis to the surface of the anterior abdominal wall and laterally to the flanks but not down the thighs.

When rupture of the membranous urethra occurs, urine or blood may pass between the layers of the triangular ligament and be present in the superficial tissues anterior to this ligament. In more serious rupture urine escapes into the deep perineal space and thence back between the prostate and rectum or thence anteriorly behind the symphysis pubis into the perivesical space between the peritoneum and transversalis fascia

The Ischiorectal Fossa The ischiorectal fossa is situated between the tuberosity of the ischium and the anus Its main affections are from abscesses from the rectum. *It has* an anterior process which runs forward between the prostate gland internally and the ischiopubic ramus externally The posterior process is its deepest extension and communicates from side to side between the coccygeal attachment of the external sphincter muscle of the anus The ischiorectal fossa is enclosed by the levator ani and coccygeus muscles on the inward side and by the obturator internus muscle on the outward side.

Development of the Organs Incident to the Formation of the Perineum The bladder is first recognizable at a stage when it receives on each side a *mesonephritic duct* and a ureter Soon the four ducts, namely, the two ducts of the mesonephron and the two ureters, become separated and the ureters move laterally. The bladder when it begins to form is tubular in shape, then it expands and is saccular in shape with the elongate urachus at its apex The urachus is continuous with the umbilicus and may in rare instances maintain this connection between the umbilicus and the bladder throughout life

The female urethra is formed by an elongation of the original connection between *the primitive bladder and the urogenital sinus* T[illegible] counterpart of the female organ and in addition the pelvic portion [illegible] the prostatic and membranous urethra The [illegible] cavernous urethra

The prostate gland originates from multiple outgrowths of the urethral epithelium The outgrowths are soon surrounded by connective tissue and smooth muscle fibers The Skene glands in the female are homologous to the prostate but are few in number and situated near the external urethral outlet

The bulbourethral glands (Cowper) of the cavernous urethra of the male are homologous to the vestibular glands (Bartholin) of the female.

The seminal vesicles arise as outpouches from the mesonephron and gain muscular walls from the mesenchyme. There is no homologous organ in the female.

Pilonidal Cyst and Sinus. Outside of the pelvic outlet in the midline of the coccygeal region, if there has been a failure of union of the ectodermic layer of the embryo, there occurs below the surface an inclusion of hair-growing tissue termed pilonidal cyst. However, as N. D. Smith has pointed out, this cyst may be situated

ectoderm is on or near the surface of the body. Surface structures have as an important function the protection of the organism from the adversities of the environment, and at least a part of this protection is obtained through the ability to perceive pain. Structures arising from the mesoderm and entoderm when stimulated do not give rise to definite localized pain A sharp pain in anorectal disease points to a pathologic condition involving the anus

Imperforation and Associated Malformations. Imperforation and the malformations associated with imperforation constitute most of the congenital disorders of the rectum. The various types of imperforations may be enumerated as the imperforations of the rectum with vesical, posterior urethral, uterine or vaginal outlet. In an occasional instance there may be a spinal outlet In females the genital outlets may open into the rectum Also the rectum may be imperforate for lack of an anal outlet, or the rectum may have difficulty in emptying, owing to stenosis of the anus and thus may empty through the vagina.

IMPERFORATE RECTUM The rectum may be absent, or its descent may be arrested at any point distal to the promontory of the sacrum The usual point of arrest is at the peritoneal reflection A fibrous cord may extend from the apex of the rectum to the anal cul-de-sac or from the imperforate rectum to the bladder or the urethra

The first symptom of an imperforate rectum after birth is absence of bowel motions. This is followed by the symptoms of obstruction of the colon

On examination there may be a normal-appearing anus and anal canal, or the anus may be absent. If the anal canal is present, the well-lubricated little finger when inserted into the rectum reveals a shallow rectum completely occluded

Imperforate rectum with vesical outlet is a rare condition. The communicating passage is narrow and lined with mucosa. It opens into the bladder, often near the trigone The diagnostic symptom is fecal (meconium-stained) urine On examination the finger is stopped at a shallow depth It is then obvious that the source of the feces-stained urine is an opening of the rectum into the urinary system. Communications other than from the rectum to the bladder are usually in the posterior urethra

In *imperforate rectum with posterior urethral outlet* the passage from the imperforate rectum may open into the prostatic or membranous urethra. Some of the patients who have this malformation attain adult life The diagnosis of imperforate rectum with vesical outlet or urethral outlet is definitely established by endoscopic examination

In *imperforate rectum with vaginal or uterine outlet* the communication usually opens into the vestibule of the vagina. The symptoms and signs are the same as those of an imperforate rectum, with the addition of the passage of feces from the vagina Often these openings may be adequate for drainage of the rectum, and consequently the patients may reach adult life The diagnosis is made by digital or endoscopic examinations once the condition is suspected.

Imperforate rectum with spinal outlet is an obstetric curiosity. These babies do not usually survive

In those who have a *urogenital outlet in the rectum,* the vagina may be normally formed but opens into the rectum, and in some cases the abnormality is unnoticed until the menstrual flow is established The bladder is absent and the ureteral orifices may be at the peritoneal reflection in the rectum. Urine in the rectum is usually well tolerated without an ascending urinary infection. The diagnosis is made by endoscopic [illegible]

In [illegible] the

nus

the sigmoid flexure there is another fold on the anterior wall which tends to obstruct the view when examinations are made. These valves are composed of connective tissue and circular muscular fibers covered with mucous membrane.

The combined length of anal and rectal canal is 4 to 5 inches (10.2 to 12.7 cm.).

RECTAL EXAMINATION. The finger can palpate the anal canal and rectum for a distance of 4 inches (10.2 cm) from the surface. Anteriorly, in men, as soon as the finger passes the sphincters, the apex of the prostate can be felt, also the membranous urethra, particularly if it contains a bougie or sound. The prostate can be outlined and its size determined. If the prostate is not enlarged, the base of the bladder above can be palpated and the tip of the finger will reach the rectovesical pouch From the upper or posterior edge of the prostate and extending from near the midline upward and outward, are the seminal vesicles. Just to the outer side of the upper end of the seminal vesicles are the lower ends of the ureters Posteriorly the coccyx and the hollow of the sacrum can be felt Laterally the finger can explore the region of the spine of the ischium, the sacrosciatic foramina, and the tuberosities

Ataxic Sphincter This is a condition in which the external sphincter lacks tone, owing to degenerative changes in the posterior nerve roots and posterior columns of the spinal cord, often as a result of tabes dorsalis or of syringomyelia The anus appears normal on inspection, but when it is separated, it remains partly open instead of closing instantly as it does normally, and then very slowly resumes its usual state of contraction When tabes dorsalis is not otherwise suspected, this symptom often gives the first indication of the disease

In some patients an ataxic sphincter, in the absence of any demonstrable lesion of the peripheral nerves or the central nervous system, is due to a prolonged use of laxatives

Rectal Shelf Masses Properly the term rectal shelf has been employed to designate that condition in which a palpable mass impinging on or attached to the anterior rectal wall causes a ledge or shelf to be felt Such a mass deserves serious evaluation because it may call attention to a lesion remote from the rectum. The mass may resemble a primary carcinoma of the rectum and thus lead to an error in diagnosis and prognosis. A patient may consult a physician because of symptoms produced by the rectal shelf or a pararectal mass without relating these symptoms to any which result from the primary lesion, or the reverse situation may be encountered The commonest causes of pararectal masses among women are lesions of the genital system, and among men lesions of the gastrointestinal tract and the stomach (carcinoma) in particular

Congenital Malformations of the Anus and Rectum. ***Persistence of Cloacal Duct.*** In persistence of the cloacal duct there is a narrow outlet from the rectum to the raphe of the perineum, scrotum, underside of penis, prostatic urethra or bladder In the female the opening may be along the perineal raphe or into the vestibule of the vagina

The rectum develops from the entoderm and the mesoderm, the anus, the proctodeum, develops as an invagination of the ectoderm The primitive rectum and the primitive anus gradually approach each other Absorption of the epithelial layers of the proctodeum and the primitive rectum permits the joining of the lumina

The conjunction of the rectum and the anus, at a point in front of the posterior end of the gut, leaves a cul-de-sac This cul-de-sac and the connecting canal are largely absorbed during fetal life Imperfect absorption is the cause of a congenital posterior rectocele. The region where this posterior cul-de-sac and the communicating canal are situated is a favorite site for the occurrence of dermoid cysts and other teratoid tumors of the rectococcygeal space.

As has been indicated, the anus and the rectum developmentally and functionally are distinct organs, arising from different layers of the embryo, and thus are subject to diseases inherent to the tissues from which they arise. The diseases of each organ present symptoms which are unlike those of diseases of the other. This is particularly true of ... of pain. The anus arises from ectoderm Any structure which arises from

hemorrhoids and polyps Some large papillae may be drawn out of the anus by the palpating finger. Attempts to pull these away with the examining fingers cause acute pain and hemorrhage

Abscesses and Ulcers. *Anorectal Abscesses.* The diseases such as fissures, ulcers, abscesses, fistulas and abrasions are often initiated by breaks in the continuity of the anorectal lining membranes resulting from trauma and not by direct invasions of the tissue by bacteria, viruses or parasites.

An anorectal or a rectal abscess develops from an injury made by the passage of formed feces of large caliber, often containing hard pellets which tear one or more of the anal crypts. These tears are common and usually heal promptly. Occasionally such a tear does not heal promptly, and then an inflammation of the crypt occurs, spreads to the surrounding tissues, and results first in the condition known as cryptitis The cryptitis either heals or proceeds to abscess formation.

The extent of the inflammation and the structures affected determine the type of anorectal abscess present. For instance, if the pus forms above the levator ani muscle, the abscess is either a *superior pelvirectal abscess* or a *retrorectal abscess,* depending on which of these spaces is occupied An abscess posterior to the levator ani muscle is an *ischiorectal abscess.*

The superior pelvirectal and retrorectal inflammations originate outside the rectum These inflammations are frequently extensions of an infection of the adjacent pelvic urogenital organs, or of the intestines Occasionally an ileitis may originate such an abscess

The studies by Hill and co-workers of structure of the anal glands offer a possible explanation of the spread of infection through these glands There is a wide individual variation as to number, depth of penetration and contour of the anal glands. Lack of complete canalization of the terminal portion of the anal glands was observed in 3 newborn infants. In some of the specimens from adults the cells lining the anal glands presented apical cytoplasmic vacuoles which stained positive for mucin

Various existing traumatic, bacterial and constitutional factors unite to permit infection to spread by way of the anal glandular system The extension of anal glands upward beyond the anorectal line into the rectal submucosa offers an explanation of the occasional occurrence of abscess and fistula in this region. The deep penetration of an anal gland extending into the internal sphincter points to possible avenues of invasion along muscle bundles, fascial planes and adjacent structures to these lines of cleavage A definite glandular cyst in an adult supports the claim that abscess and fistula may develop without communication with the anal canal

Symptoms In the superior pelvirectal and retrorectal abscesses pain is deep but not intense Prostration is often profound, for large quantities of pus can accumulate in these spaces There may be intermittent fever. These abscesses are often the cause of the so-called pyrexia of unknown origin In a few who have these abscesses the temperature may be as high as 105 F (40.5 C) or more.

If the abscess has had its origin in a pelvic organ, for instance, an ulcerative colitis, or from an ileitis, or if it has originated in the prostate and extended, the whole side of the buttocks may become exceedingly tender, reddened and swollen. There often are fever and an accompanying diarrhea.

An abscess arising in the anus which extends to the perianal tissues is characterized by local redness, swelling, pain and hot skin similar to the manifestations of a superficial abscess elsewhere

Examination. On examination the anal orifice and buttocks often appear normal On digital examination of the rectum above the anorectal line, a soft tender mass may be palpated The leukocytes vary in number from normal to 30,000 per cubic millimeter of blood.

The anus may be completely formed, but occluded at the anorectal line by a thin, elastic diaphragm of fibrous or mucocutaneous tissue due to the persistence of the anorectal membrane. In these infants there are no bowel motions. Examination often reveals an impulse or a fluctuation of the distended rectum.

The diagnosis of imperforate anus is usually made by inspection and palpation

CONGENITAL STENOSIS OF ANUS The normal anus of an infant should admit without difficulty the lubricated little finger. The canal may be narrow throughout or segmentally. The narrowing may be so slight that the passage of soft feces causes no difficulty, but harder masses give rise to constipation and straining

The diagnosis is made by digital examination. Normally the anal canal varies in caliber, and due allowances are given for these normal variations.

Anal Ulcers (Fissures). Anal fissures and ulcers are usually manifested in the third, fourth and fifth decades Occasionally they are present in children, but rarely in the aged Two men have anal fissures or ulcers to each woman so affected Nine of every 10 anal ulcers or fissures occur in the posterior portion of the canal.

Anal fissures or ulcers are almost always caused by fecal trauma However, trauma also may result from sharp particulate matter or a fishbone in the feces A common source of anal trauma is the introduction of a syringe tip An uncommon source, but nevertheless one that does occur, is sodomy. Sodomy may be followed by gonorrheal proctitis and ulcers Injury and destruction of an anal crypt may result in ulceration

The characteristic symptoms are bleeding with bowel motions, and pain occurring from a few minutes to a half hour after bowel movement The pain continues for variable lengths of time and then entirely or partially subsides until the next bowel movement There is a wide variation in the degree of pain. Some patients may have little or no pain from an anal ulcer or fissure

On digital examination the anus is exceedingly tender When the sphincter is spread open, the ulcer is seen to be oval or circular and just within the grasp of the muscle Often it has a superficial fistulous tract leading toward the skin surface and the teatlike process known as the sentinel pile at the skin margin of the ulcer.

A chancre of the anus may closely resemble the usual type of anal ulcer Anal chancres occur more frequently in women than in men

Cryptitis. The anal crypts are small pockets distributed about the anorectal line Inflammation of these pockets is termed cryptitis This inflammation has been designated infected hemorrhoids.

The anal crypts have their openings directed inward They are subjected to trauma by the passing feces Following trauma, mucosal abrasions within the crypts may originate an inflammatory reaction. These reactions often terminate in pararectal abscess.

The symptoms of cryptitis closely resemble those of ulcer or fissure There is pain, commencing after a bowel movement Pains referred to the perineum, the urogenital region, the sacrum and coccyx, or down the legs are common On examination there is tenderness along the anorectal line

Cryptitis is not usually an inflammation of a single crypt, but an inflammatory reaction that has originated in a crypt and then spread along the anorectal line. The proctoscopic findings are characteristic enough for diagnosis by an experienced examiner

Papillitis. Papillitis is an inflammation of the anal papillae The anal papillae are often found to be hypertrophied. This enlargement without symptoms is considered to be an incidental condition.

Enlarged papillae may be torn by the stool, resulting in sharp pain in the anus and bleeding Usually there are no symptoms of papillitis.

On rectal palpation the finger may perceive soft or firm, teatlike projections at the anorectal line. Large papillae may cause some examiners to suspect internal

is differentiated from perianal tuberculosis by biopsy. Usually, however, the diagnostician has little doubt of the differentiation even without laboratory aid.

The prognosis is never good. The condition usually is secondary to tuberculosis in some other part of the body, and even when the ulcers heal, there is a constant danger of reinfection Often, too, the disease advances despite all treatment

Tuberculosis of the Rectum. Tuberculosis of the rectum practically always is secondary to an infection elsewhere in the body, the lungs being the usual primary seat. The rectum is involved more rarely than the intestinal regions above but more frequently than the anus

Three forms of rectal tuberculosis are described: the miliary, the ulcerative and the hyperplastic

Miliary tuberculosis of the rectum is rare and always is part of a generalized tuberculosis Multiple tubercles form beneath the mucosa and these coalesce and slough to form irregular ulcers Sometimes these ulcers will burrow beneath the mucosa to form small fistulas.

In *tuberculous ulceration* of the rectum the tubercle bacilli are carried to the rectal mucosa through the lymphatics and there form tubercles As these break down and coalesce, they form small ulcers The edges of these ulcers undergo a progressive degeneration which leads to a constant increase in their size until there are large ulcerations.

Secondary infection of the ulcers may cause them to perforate the musculature of the rectum and even of the peritoneum, resulting in tuberculous abscesses of the perirectal tissues and subsequent fistulas which may extend into the bladder or other contiguous organs with the production of a tuberculous peritonitis

The symptoms of tuberculous ulceration of the rectum are cramplike pains during bowel movements, often accompanied by tenesmus, and frequent stools, sometimes numbering as many as 30 during the 24 hours Contained with the stool is a mucopurulent, blood-tinged, fetid discharge The discharge, scanty in the beginning, increases in quantity until it becomes profuse. When the discharge is copious, it is thin and irritating to the anal skin

On examination the ulcers are irregular, gray, and rough-appearing with slightly thickened, irregular and undermined edges The mucosa between the ulcers is likely to be inflamed and edematous

The diagnosis of the disease is based on identification of the tubercle bacilli by cultural means, guinea pig inoculation and on the characteristic appearance of the ulcers and the fact that the disease occurs in a patient who has active pulmonary tuberculosis or tuberculosis of some other part of the body

Hyperplastic tuberculosis of the rectum is a rare form of the disease It is characterized by a localizing thickening of the intestinal wall due to a round cell infiltration and the massive deposit of fibrous tissue This condition, commonly known as tuberculoma, may resemble malignant disease. The treatment is surgical

Tuberculous Pararectal Abscess. The tuberculous pararectal abscess has an insidious onset. When it has fully developed, there is no pain or tenderness over the infected region Usually the only symptom will be distortion of the part from the accumulation of pus The condition always is secondary to tuberculosis in some other part of the body, usually the lungs, and it may occur during the course of a tuberculous ulceration of the rectum An accumulation of fluid beneath the skin of the buttocks and near the anal margin, without acute symptoms, arouses suspicion of a tuberculous abscess, particularly in a person who has pulmonary tuberculosis

Tuberculous Fistulas. These fistulas result from the evacuation of pus from a tuberculous abscess The fistulas may connect with the skin of the buttocks or with any organ adjacent to the rectum and anus.

Syphilis. There may be itching early, but the chancre or ulcer is painless unless it is within the grasp of the sphincter or is complicated by a mixed infection.

When the abscess has extended to involve the perianal tissues, particularly in the presence of an ileitis or chronic ulcerative colitis, there may be swelling and redness of the skin and induration of the tissues of one side of the buttocks. When these manifestations are present, rectal examinations may be impossible because of the tenderness and pain.

The superficial abscess can be recognized from the mildness of its manifestations. Rectal examinations are painful but usually can be performed if care is exercised during the examination. In the presence of the superficial abscess, the inside of the rectum feels normal and it is not tender

DIAGNOSIS The diagnosis of an acute, superficial abscess is made from the presence of pain, tenderness and redness of the affected parts Fluctuation may be present

The diagnosis of deep abscess such as pelvirectal and retrorectal abscesses may be uncertain The prostration, high fever and leukocytosis, and often the sensation of weight and heaviness in the pelvis, draw attention to this region. These symptoms accompanied by the presence of a tender rectal mass justify a presumptive diagnosis In due time, after exercise of judgment and caution, an exploratory incision may be required for both diagnosis and proper treatment

Anorectal Tuberculosis. A tuberculous infection of the rectum and adjacent tissues occurs in a patient who has swallowed infected milk or sputum, and thus an opportunity has been rendered the bacillus to invade the tissues of the rectum The tubercle bacillus may invade the anorectal regions from an anorectal focus through the lymphatics, through the blood stream and by direct extension from contiguous organs from inside the pelvis

Tuberculosis of the Anus. *Tuberculosis of the perianal skin* occurs as lesions, miliary, ulcerative, lupoid and papillary (verrucous) The lupoid and papillary forms are rarely observed

Miliary lesions of the anus are a part of an advanced and generalized infection in some other part of the body Multiple minute nodules form beneath the epidermis and gradually coalesce and break down to become the ulcerative type of tuberculosis. Diagnosis is established by biopsy and guinea pig inoculation The prognosis is poor

Ulcerative tuberculosis of the anus is the commonest form of the disease It may be secondary to a focus in the lungs or intestines but is more likely to be a primary infection than is tuberculosis of the rectum Small nodules form in the skin and then coalesce and disintegrate to become ulcerations The ulcerations may be single or multiple, and at times are epitomized by massive ulceration that involves the entire perianal region The individual ulcers usually are superficial but may involve all of the layers of the skin. Their shape is irregular and they have a distinct margin depressed below the surface of the raised base Sloughing and undermined edges are characteristic

Patients who have severe exudative and destructive pulmonary disease are more subject to anal fistulas than patients who have the productive type of the disease. The perianal abscess either precedes, or concurs with, a progressive or regressive modification of the pulmonary process Patients who have severe tuberculosis may exhibit multiple anal fistulas surrounded by granulation tissue, extensive zones of infiltration and detachment of skin at the external openings, whereas in the fibrous type of pulmonary tuberculosis the fistulas are benign When ulcerative pulmonary tuberculosis exists, specimens obtained by scraping the fistulous tract often yield tubercle bacilli In the fibrous type of pulmonary tuberculosis with negative sputum positive results are less frequent Tissues surrounding anal fistula often yield positive evidence of tuberculosis. The anatomic and clinical observations indicate that the perianal tuberculous abscess is probably of hematogenous origin

The diagnosis is established by biopsy and guinea pig inoculation Epithelioma

opening but no external opening. Many variations of these fistulas exist (Fig. 7-2). Often there are multiple external openings which communicate with each other and with an internal opening.

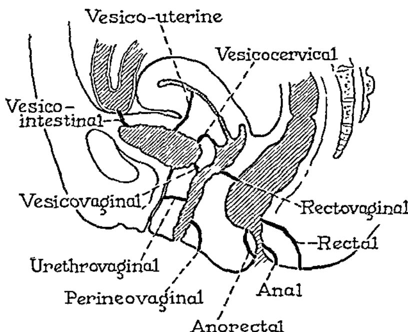

Fig 7-2. Common sites for anal, anorectal, rectovaginal, vesicocervical, vesicouterine, perineovaginal and urethrovaginal fistulas

The genesis of fistula is a pyogenic organism with the formation of an abscess. The organism present is usually the staphylococcus, not the tubercle bacillus.

Inflammation of the crypts of Morgagni extending to the perirectal tissue may terminate in formation of abscess The abscess may rupture into a pelvic organ or through the skin of the buttocks and thus establish a fistula An abscess of this type may rupture into the vagina, the uterus, the urethra, the prostate gland or the bladder. The external opening of these fistulas does not bear a constant relationship to the position of the internal opening There may be many external openings over both buttocks and thighs

SYMPTOMS Fistulization about the anus and rectum is characteristically secondary to the rupture of an acute abscess somewhere about the rectum or the genitalia. The symptoms of the abscess are obtained from the history and are often summarized by the presence of pain, redness, swelling and fever. The abscess opened spontaneously or was lanced, and relief from symptoms followed the drainage After the rupture or lancing of the abscess a small opening persisted in the buttocks from which there was constant oozing of a purulent or serous discharge which in time ceased After a lapse of time another acute abscess developed This sequence of events may be repeated with the maintenance of a single fistula; or, with formation of each new abscess, new fistulas may be added until the entire buttocks and perirectal tissues are involved in fistulas.

EXAMINATION On examination the external opening of the fistula is readily found Often a probe may be gently worked through the fistulous tract until it emerges through the internal opening in the rectum under direct visualization through an endoscope. Often, however, the tract is tortuous and it is impossible to work the probe through the tract in an unanesthetized or, on occasion, an anesthetized patient. The probable internal opening may be discovered by palpating with the finger from within the rectum.

If the lesion is single and fairly characteristic of chancre, a presumptive diagnosis can be made A definite diagnosis depends on positive results of darkfield examination. Serologic reactions of the blood are seldom positive before the second week or later.

Condyloma Latum. This is a secondary manifestation of syphilis occurring within the anus or in the perianal skin and characterized by wartlike elevations occurring singly or in groups.

A pearly white, flat, oval or rounded patch begins on the skin surface and multiplies These plaques have a tendency to form large fungating masses which may encircle the anus and extend to the vulva or to the scrotum The masses are broad, flat, warty elevations with sharply defined edges which rise at right angles from the skin The surface is flat and covered with a glistening, grayish necrotic membrane Diagnosis depends on a positive Wassermann reaction, combined with the history of a primary lesion and the presence of the wartlike plaques just described

Rectal Injuries and Foreign Bodies. ***Rectal Injuries.*** Spontaneous rupture of the rectum may occur as the result of crushing blows to the abdomen or pelvis, and from accidental dilatation from the nozzle of a pneumatic hose entering the rectum Many different sorts of anorectal injuries are sustained in farm accidents; for instance, *falling astride a fence post, and falling on the handle of a pitchfork.*

The symptoms are severe abdominal pain, prostration, shock and hemorrhage. Diagnosis is not difficult, as a rule, and should be made early so that surgical intervention may be performed immediately to prevent or to alleviate peritonitis

Foreign Bodies. Foreign bodies find lodgment in the rectum usually by being *swallowed, but they may be inserted through the anus In those who have mental* diseases all manner of objects may be packed in the rectum Rarely, they may gain entrance from a contiguous organ or they may form within the intestinal tract (gallstones, fecaliths)

Symptoms are extremely variable and depend to a great extent on the size and shape of the object within the rectum. Small objects, such as fishbones, which become caught within the anus cause a sudden, sharp and constant pain

The diagnosis depends entirely on rectal examination. Endoscopic and roentgenologic examination should be resorted to whenever rectal examination leaves the least doubt as to the nature, extent or situation of the offending body.

Anal Stenosis and Contracted Anus (Pectenosis and Anal Fibrosis) The inflammatory stricture follows extensive removal of the anal skin, and superimposed infection may result from (1) hemorrhoidectomy, (2) trauma, (3) the injections in the treatment of pruritus and hemorrhoids, (4) the excision of fistulas and anal condylomas, (5) chronic ulcerative colitis, (6) lymphopathia venereum and (7) irradiation therapy The stricture often is tubular and may be from 1 inch to 3 or 4 inches (2 5 cm to 7 6 or 10 2 cm) in length, and the strictured lumen may be measured in millimeters

Bowel movements are difficult and painful In some cases blood and pus are passed from the rectum with stool, or sometimes as a leakage, independently of bowel movement

The anus and rectum are of small caliber and very tender, so that digital examination may be impossible Often a proctologist can pass an instrument of small caliber for endoscopic examination of a patient who cannot permit a digital examination.

The diagnosis is evident from the foregoing findings. The treatment is *dilatation* except in those who have chronic ulcerative colitis, active lymphopathia venereum or irradiation therapy

Anorectal Fistula. A *complete anorectal fistula* implies an internal opening in the anus or rectum or at the anorectal line, and an external opening in the skin surface near the anal orifice or in the buttocks. An *incomplete fistula* has an internal

On inspection and palpation there is a livid, firm, tender swelling beneath the smooth, shiny skin After the acute symptoms have subsided, the swelling will seem shotlike, a characteristic that will persist for a long period There are sometimes erosion of the overlying skin and bleeding from the thrombotic hemorrhoids. A swelling on one side of the anus which is tender and painful, firm and livid, beneath smooth, shiny skin is diagnostic.

Internal Hemorrhoids. The etiologic factors capable of producing internal hemorrhoids are heavy lifting, standing posture, sedentary habits, heredity, portal hypertension, constipation, straining at stool, and infection A low-grade, long-standing infection weakens the venules and veins of the rectum so that the weakened lining of the veins ruptures and acute thrombosis results After repeated thromboses occur, there is prolapse which is constant, and after bowel movements the prolapsing mass is replaced regularly with attendant trauma. The prolapsing mass increases in size and protrudes through the sphincter muscle The muscle may lose its tone, owing to continued pressure and long-standing disease.

Without thrombosis internal hemorrhoids are painless. Bleeding occurs at bowel movements Blood may squirt in a small stream as the patient strains The quantity of blood lost at any bowel motion is seldom great, but the staining of the water in the bowl may give the impression of a large hemorrhage Internal hemorrhoids will occasionally bleed spontaneously, for instance, while the patient is pursuing the daily tasks.

A prolapse of the mucous membranes may occur at bowel motion The prolapsing mass often retracts without assistance When the prolapse is marked, however, the mass will not return within the lumen of the rectum and must be replaced by the patient A prolapse hemorrhoid which remains outside the anal canal will cause a constant dragging pain in the rectum, and there may be perianal edema.

The examining finger can feel large internal piles or sclerosed piles but not small ones The diagnosis is made by proctosigmoidoscopic examination.

PROLAPSED INTERNAL HEMORRHOIDS. Prolapsed internal hemorrhoids may get caught in the grasp of the anal sphincter and become edematous. To replace prolapsed hemorrhoids, ask the patient to lie on the left side Bathe the hemorrhoids with cold water to reduce the edema Apply petroleum jelly liberally with cotton Exert pressure on the protrusion with one hand while the other hand is easing the constriction of the edematous folds of the anus. If the edema is so great that the hemorrhoids cannot be returned, it may be necessary to anesthetize the sphincter with some local anesthetic agent

If the hemorrhoidal mass cannot be thus replaced, the condition is termed strangulated piles or hemorrhoids This condition requires hospitalization and appropriate treatment

Proctitis and Proctosigmoiditis. Proctitis is an inflammation of the rectum. Sigmoiditis is an inflammation of the sigmoid flexure, that portion of the colon which extends from the crest of the ilium to the level of the third sacral vertebra Inflammation of both the rectum and sigmoid is known as proctosigmoiditis

Proctitis or proctosigmoiditis may result from constitutional disorders such as diarrhea and fever caused by the exanthems, influenza and hepatic diseases Any chronic disease accompanied by diarrhea may cause proctosigmoiditis. All of the acute infectious dysenterial diseases are accompanied by proctosigmoiditis.

The manifestations are often those of hemorrhoids, the hemorrhoidal irritation having been produced by tenesmus and the frequent passage of watery bowel motions which may contain blood and mucus.

Diagnosis is established by the presence, on endoscopic examination, of a reddened, inflamed mucous membrane of the rectum and rectosigmoid. Time and repeated observations may be necessary to be sure that the disorder is not an early stage of chronic ulcerative colitis

DIAGNOSIS. The diagnosis is made from the findings revealed by physical and endoscopic examinations.

Hemorrhoids. Hemorrhoids appear exter... ternal hem... belo ...

...from the superior hemor-

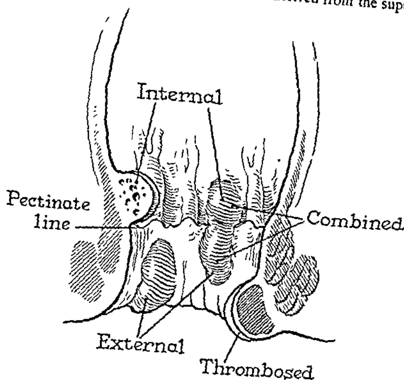

Fig 7-3 Hemorrhoids

rhoidal vein and are situated above the anorectal line They are covered with mucosa

External Hemorrhoids. External hemorrhoids comprise skin tabs and varicosities of the anal veins Since man walks on his hind legs, the cause of external hem... ...present in four-footed animals. The incidence ... men and women ... objectionable because of the difficulty they cause in efficient cleansing of the parts. They usually do not produce symptoms

Varicosities are seen as bluish swellings just within the anal canal or at the anal margin and are soft and compressible

The foregoing described diagnostic findings are unmistakable and symptoms are usually absent

THROMBOTIC EXTERNAL HEMORRHOIDS Thrombosis of external hemorrhoids results from a strain or traumatism to the thin-walled anal veins Coughing, sneezing, lifting, or straining at stool may cause one or more of the coats of a diseased vein to give way, to be followed by formation of clot within the walls of the vessel or in the surrounding connective tissue Once the thrombus is formed, it may remain, and the swelling and pain gradually cease in from 3 to 10 days If rapid distention of the veins takes place, rupture may follow

Immediately following the rupture there is a feeling of continuous discomfort. Sometimes throbbing, burning pain in the anus ensues and continues. As the pain and soreness develop, it becomes more and more difficult to sit in comfort or to move the bowels. Pressure on the tumor is painful. The discomfort continues to be severe for 2 or 3 days and then gradually subsides.

[illegible] of more proximal segments of the bowel. These masses

Pruritus Ani [illegible] of nervous tension and irritability. The unusual causes of pruritus ani are diabetes, infestation with pinworms (see Diseases of the Colon, Chapter 13), pediculosis pubis, fungous or other infections of the skin, general dermatosis and infections of the anorectal region. A severe anal pruritus may result from the application of salve for the treatment of hemorrhoids.

Localized itching may be mild and present only occasionally, or it may be continuous and severe. The itch is more intense after the patient has retired for the night, or perhaps after he or she has been sleeping for half of the night The itch may be agonizing, and there is an overwhelming desire to scratch the affected area The patient scratches himself unconsciously when awake or during light sleep

Unbearable and constant itching, in time, because of the consequent loss of sleep and persistent irritability, will lead to physical fatigue and mental exhaustion

On examination, interspersed about the anus will be excoriations from scratching The skin about the anus is often reddened, swollen and either dry or moist In advanced severe pruritus ani the skin assumes a leathery appearance Lichenification, a pale and blanched appearance because of a loss of pigmentation, ensues. The radiating skin folds are likely to be edematous and hypertrophied, and the sulci between to become cracked or fissured

The diagnosis of pruritus ani depends on the history of itching about the anus and the findings revealed on physical examination

Tumors of the Anorectal Regions. ***Benign Tumor.*** *Verruca acuminatum of the anus* has the synonymous names anal wart, papilloma and verruca. Warts and papillomas that occur about the margin of the anus and within the anal canal are often called venereal warts Condyloma latum, however, is the only one of venereal origin

The papillomas consist of connective tissue and blood vessels covered with stratified epithelium They arise from hypertrophy of the papillae of the skin and are caused by irritating discharges such as occur in gonorrhea, hemorrhoids, proctitis and colitis. Verruca acuminatum is an excrescence which begins on one side of the anus and often spreads rapidly until it surrounds the anus as a large cauliflower-like tumor attached to the skin by many pedicles The growths are soft and pliable, of a pale pink color, and bleed freely when injured They are distinguished from epitheliomas by the absence of induration at the base or ulceration of the surface

Verruca acuminatum and papillomas are to be distinguished from the highly malignant papillomatous forms of anal epitheliomas which are situated at the anal verge or within the anal canal. Likewise they are differentiated from protruding hypertrophied anal papillae which may protrude from the anus. The diagnosis is established by biopsy and histologic study

Malignant Tumors. Anal Carcinoma (Epithelioma). Anal carcinoma arises from the squamous cell epithelium of the skin and mucocutaneous junction and thus *is an epidermoid carcinoma having all the characteristics of carcinoma of the skin* and of lesions of mucocutaneous junctions such as the lip or vulva Most of the growths are ulcerating lesions, but they may appear as cauliflower-like masses protruding from the anus

The complaint may be of anal discomfort, with or without relation to stool, and the passage of large quantities of fresh blood. In addition the patient may report the presence of a tag or growth within or near the anal orifice which has suddenly enlarged and become painful These features are highly suggestive of an anal lesion, and the odds are greatly in favor of anal fissure, since anal epithelioma occurs only rarely. Nevertheless the possibility of epithelioma must be considered in all middle aged patients of either sex

Gonorrhea. Gonorrhea of the rectum is uncommon. The gonococcus may gain entrance to the anus and rectum by inoculation of pus from an infected urethra, by pederasty or by the contamination of instruments. Diagnosis is made only on the basis of positive cultures.

Prolapse, Protrusion and Procidentia of the Rectum and Sigmoid Colon. Prolapse or procidentia is a descent of one portion of the rectum or anal canal into or through another In complete prolapse there is an intussusception of the rectum

Prolapse of the rectum is classified as *incomplete or partial prolapse* when only the mucous membrane is involved, and *complete prolapse or procidentia* when all of the coats of the bowel form a part of the prolapse When the colon becomes involved, the prolapse is termed a *colonic procidentia,* since the anus does not have three coats. A patient can have an anal prolapse but not an anal procidentia.

The common causes of prolapse and procidentia are either intrinsic or extrinsic to the bowel The intrinsic conditions causing prolapse and procidentia are hemorrhoids, polyps, neoplasms, foreign bodies and sodomy. Extrinsic conditions are parturition, tumors and displacements of the uterus, hypertrophy and tumors of the prostate, visceroptosis, intra-abdominal tumors, prolonged vomiting, coughing or crying, tightly applied belts and corsets, certain violent exercises, urethral calculus and urethral stricture, and phimosis.

Prolapse occurs in children less than 5 years of age and in the aged who have debilitating disease and nutritional disorders with a loss of ischiorectal fat.

Disease of the spinal cord resulting in paralysis or relaxation of the anal sphincter or levator ani muscle, such as tabes dorsalis, predisposes to prolapse and procidentia

In the beginning there is protrusion only at stool, a prolapse. At first the protrusion is of slight degree The protrusion may gradually become greater until several inches or more of the bowel may remain outside. Subsequently the external sphincter becomes more and more atonic until it becomes difficult or impossible to keep the bowel in its proper place. Often the condition is intermittent. Discomfort, described as a bearing-down sensation, is present whenever the mass is outside of the body, and it may be present at other times.

The mucosal prolapse is a redundancy of the mucosa, which protrudes through the anus at stool. It is bright red, moist and glistening, and has small hemorrhagic areas on its surface Protrusion through the anus occurs at stool and the protruded mass may return within the sphincter spontaneously or may remain outside until pushed within Protrusions which have been present for a long period may remain outside of the anus When this occurs, the reddened congested mucosa often becomes eroded and ulcerates With the passage of time the mucosa turns pale and assumes a leathery appearance and the sphincter loses its tone.

DIAGNOSIS. Prolapse of the rectum which does not extend beyond the anus is diagnosed by proctoscopic examination An abnormal looseness or wrinkled swelling of the mucosa will be seen and this may involve a segment of the rectum or its entire circumference

Procidentia recti, the displacement of the rectum with all of its coats into its lumen or through the anus, is distinguishable by the presence of the musculature, shown by concentric rings in the mass. These rings constitute the differential point from a prolapse protruding from the anus in which folds radiating from the anus are seen in the mass. The mucosa of the procidentia, after long exposure outside of the body, becomes thickened and firm.

A procidentia of the rectum which does not protrude from the body can be palpated with the finger and is felt as a mass, with a lateral sulcus, filling the rectum.

A sigmoidal procidentia presents the same characteristics as those of the rectum

The disease is manifested by a cluster of small erosions (eroded vesicles) on the glans penis or corona, sometimes associated with a group of typical herpetic vesicles on the shaft Herpetic infection of the genitalia of women, as of men, may be primary or recurrent The primary disease is manifested by the appearance of superficial erosions on the labia majora, labia minora and distal vaginal mucous membrane These ulcers are tender and covered by a grayish yellow membrane. The annoying discomfort usually subsides within a few days but may persist for a week or two There is a tendency for the disease to recur with similar erosions of clustered vesicles revealing an ulcerated region covered by the grayish yellow membrane.

Phimosis. Phimosis, classified as (1) congenital and (2) inflammatory, is ordinarily a symptomless defect in the preputial orifice characterized by muzzling or closure of the skin over the distal end of the penis so that the skin cannot be drawn back over the glans. Phimosis late in life may give rise to symptoms as follows: (1) retention of smegma, (2) preputial concretions, (3) adhesions, (4) balanoposthitis, (5) paraphimosis, (6) gangrenous belanoposthitis and (7) carcinoma.

Smegma accumulates behind the adhesions slowly in some persons, rapidly in others. The retention of smegma is a factor which predisposes to balanoposthitis and probably carcinoma Retention and ammoniacal decomposition of drops of urine, mingled with smegma, are the usual cause of the formation of preputial concretions and odors The tight foreskin, as the result of low-grade infection, forms adhesions to the corona and often over much of the glans and thus increases the difficulty in keeping the penis clean if such be desired by the patient.

Balanoposthitis. Balanoposthitis is an inflammation of the preputial cavity The membrane becomes reddened, mottled and moist The epithelium comes off in patches, leaving irregular excoriations which ulcerate and discharge pus There is a burning soreness with itching intensified by urination. Shallow ulcerations may occur In the severe forms of the disease there are fever and inguinal adenitis In a chronic balanitis of phimosis the mucous surface of the prepuce is granular and may become condylomatous.

In localized perimeatal balanitis of the tight meatus the inflammation may extend to involve the frenum. In time the meatus becomes so dense that the lesion cannot be differentiated from carcinoma except by biopsy.

Balanitis is obvious. The diseases to be distinguished are herpes progenitalis, lymphogranuloma inguinale, chancroid, chancre, tuberculosis and carcinoma.

Paraphimosis. This condition is characterized by a tight retracted prepuce which will not return over the swollen glans At times two folds appear, the fold nearer the root of the penis containing the constriction which ulcerates

Before the edema becomes fixed, the prepuce can be replaced in two stages, thus Evacuate the edema from the glans and foreskin to the subcutaneous tissue of the shaft of the penis by squeezing it from the glans toward the shaft Then seize the penis behind the paraphimosis in the fork between the index and middle fingers of the two hands With each thumb make pressure on the glans laterally, not from before backward, pressing the remaining edema slowly from the glans and gently urging the glans into the ring of tight foreskin It slips back suddenly If the prepuce cannot be reduced, the constricting ring must be cut

Gangrene of the penis and scrotum may occur as the result of a virulent infection of the skin and subcutaneous tissues of the debilitated and the aged man

Tuberculosis. Tuberculosis of the skin of the penis is said to occur by contact inoculation either orally or genitally. Either of these modes of infection must be rare Sexual relations continue between spouses during the early years of renal tuberculosis without resultant inoculation The disease may spread locally into the anterior urethra but no further unless stricture results

Lupus and the other forms of cutaneous tuberculosis may appear on the penis

Anal epithelioma, as the disease progresses, ulcerates, discharges foul, irritating, putrid material, bleeds on the slightest trauma, and causes severe pain and tenesmus on defecation. At its various stages anal carcinoma may resemble anal fissure, lymphogranuloma venereum, tuberculous and syphilitic lesions. A biopsy should be performed to prove the diagnosis.

The prognosis is bad, regardless of the treatment instituted. Often these lesions develop into large ulcerating, sloughing lesions which cause an indescribable degree of severe and constant pain The tumor ulcerates widely, into the pelvic viscera and often into the bladder. The malodorous blood discharge and the widely ulcerated perineal region are unavoidable despite any known treatment.

THE MALE GENITAL ORGANS

THE PENIS

Congenital Malformations. Either the absence or the doubling of the penis is very rare The penis may remain rudimentary If the lips of the slitlike urogenital opening on the undersurface of the penis fail to fuse anywhere along their extent, hypospadias results; this is a common occurrence in false hermaphroditism simulating the female type

Priapism. Priapism may be defined as persistent, painful, abnormal erection of the penis without sexual desire It exists in three forms. (1) the purely neurofunctional priapism, (2) that which results from disturbances in the local circulation and (3) that of unknown causes The first form is observed after injury of the nervous channels, as in fractures and dislocations of the vertebral column involving compression of the spinal cord, in tuberculosis or tumors of the spinal cord; in tabes dorsalis, and occasionally in other diseases of the central nervous system

Priapism of local origin is observed in cavernitis due to gonorrhea, to vesical stone, or to phagedenic ulcer of the prepuce; in the presence of neoplasm of the penis, which has invaded the corpora cavernosa, and after trauma with hematoma in the corpora cavernosa There is also priapism in leukemia, hemophilia, typhoid fever, tuberculosis, sepsis and acute articular rheumatism Priapism is often accompanied with severe pain It may become complicated by gangrene

Chordee. When the urethra is inflamed, the exudate may involve the corpus spongiosum surrounding it and prevent it from expanding In erection the organ assumes a downward curve, a condition designated as chordee It disappears with the subsidence of the inflammation

Diseases of the Skin and Subcutaneous Tissues of the Penis. The skin of the penis is thin, loose, free from hair except at the root, and has beneath it some fibers of the dartos muscle. The skin projects over the glans, forming the prepuce, and is attached to the neck or collum glandis and underneath as far forward as the urethra, forming the frenum The connective tissue beneath the skin is loose and free from fat A fibrous sheath (Buck's fascia) surrounds the corpora cavernosa and corpus spongiosum and binds them together

The lymphatics of the prepuce and skin drain into the inguinal nodes, those of the glans empty into the nodes just inside the abdomen Since the lymphatic radicles anastomose at the root of the penis, a lesion on one side of the organ may involve the lymphatic nodes in the opposite inguinal region

There are sebaceous glands in the skin of the penis near the skin of the scrotum which may become infected, red, and swollen and discharge a tiny drop of pus Cysts may occur in these glands A chancre on the skin over the shaft of the penis is rare. Viral lesions caused by the psittacosis-lymphogranuloma venereum group rarely occur on the penile skin

Herpes Progenitalis. Herpes progenitalis is a vesicular eruption occurring over the genitalia of men and women. It is caused by the herpes simplex group of viruses It occurs more commonly on the penile skin than on the genitalia of women. It often follows sexual intercourse.

cavernosa may occur. It affects only the laterodorsal terminal two thirds of the erectile bodies. The condition is of unknown origin.

The disease begins with a mild pain on erection or with a painless deviation of the erect penis The pain may be short-lived, and without treatment it will cease within a year. The deviation on erection, upward or to one side, increases for a time and then often tends to grow less. The patient ceases to be alarmed and accommodates himself to the permanent deflection Those who have extensive lesions may be unable to have erections. Flaccidity of the corpora, distal to the lesion, is frequent and often constitutes the chief complaint

The lesion may be so small as to be impalpable in the flaccid penis and is made apparent only by the deflection on erection. When the lesion is palpable, it is hard and flat and somewhat irregular and is within the corpus.

Fracture of the Penis and Extravasation of Urine. Fracture or rupture of the corpora cavernosa may occur from violence. The extravasated blood is absorbed and the laceration heals with a scar In erection this part does not expand, hence deformity and distortion with interference of function may result

Urine may invade the penis beneath the fibrous sheath but does not invade the glans because the sheath stops at the collum glandis (see Perineal Fascia and Muscles, p 393)

Benign Tumors of the Skin of the Penis. Papillomas of the skin of the penis, the so-called venereal warts, appear within the tight preputial cavity or, in the female, within the vulva They may attain an enormous size and become malignant. All urethral papillomas should be suspected of malignancy.

Condylomata lata, broad masses of papillomas about the moist creases of the penis, the scrotum and especially the anus, are usually due to syphilis.

Lipoma may occur in the perineum where it forms a bosselated ovoidal mass.

Malignant Tumors of the Penis. Cancer. Epithelioma or a squamous cell carcinoma of the penis is a slowly progressive tumor which often does not metastasize readily The average age at the time of the first symptom is 50 years. No authentic instance of the disease has been reported in a Hebrew circumcised at birth. Jewish women rarely have carcinoma of the cervix These two observations may indicate that here are two diseases not common to Jews At least, the value of circumcision as a preventive of carcinoma of the penis will have to stand on its own merits, it does not receive impetus by the citing of Jewish records. It is in non-Jewish persons that the disease appears most frequently. There is no doubt, however, that a long or a tight prepuce is present in most of those who have carcinoma of the penis

The common situation of cancer of the penis is about the corona of the glans The lesion may be papillary The tumor becomes infected early, ulcerates and sloughs Penile cancer usually metastasizes uniformly to the lymph nodes Occasionally a highly malignant lesion will metastasize to the bones and to the lungs.

The tumor often is hidden from the patient's view by the tight prepuce The complaints are referable to the infection In some instances the initial symptom is a lump under the prepuce or the presence of a bloody discharge from the phimosis

On examination, not infrequently it is necessary to make a dorsal slit in the prepuce in order to secure sufficient retraction for an adequate inspection of all the parts The appearance of the tumor and its palpable features is variable, from a small lump to a large, extensive, fungating, ulcerating lesion. The inguinal lymph nodes are often palpable. The enlargement of these nodes may be due to the malignant disease or to infection.

The venereal wart, condylomas, granuloma inguinale, and tuberculous lesions resemble cancer in some instances so closely that there is no safe criterion for the diagnosis except biopsy. Involvement of the lymph nodes can be proved by biopsy. If the corpora are definitely invaded with carcinoma, it must be assumed that the

or the scrotum Multiple tuberculous nodules have occurred in the corpora cavernosa and corpus spongiosum.

Cutaneous tuberculosis situated on the external genitalia of men has to be distinguished from soft chancre Soft chancre, in men, may occur on any part of the anorectal skin.

Soft Chancre. There are three infections of the external genitalia and anorectal regions of both men and women which are characterized by ulcerations and inguinal lymph-node involvement and abscess formation. (1) soft chancre, (2) granuloma inguinale and (3) lymphopathia venereum. The similarity of manifestations of these diseases and in the terminologies is confusing (see Diseases of the Female Genitalia, p 440).

A soft chancre results from an infection by the bacterium *Hemophilus ducreyi* (Ducrey's bacillus) Granuloma inguinale is caused by a bacterial infection; the specific bacterium is unknown but it characteristically forms Donovania granulomatis Lymphogranuloma venereum is caused by a filtrable virus

The soft chancre or chancroid is caused by *Hemophilus ducreyi* This organism appears in the purulent discharge from the soft chancre or chancroid of a venereal disease for which it is responsible. The morphologic structure of the organisms in local lesions is characteristic, chains of small gram-negative bacilli occur in strands. A saline suspension of killed *Hemophilus ducreyi* serves as a good antigen for diagnostic cutaneous tests

Soft chancre with associated abscess in inguinal lymph nodes is perhaps 15 times as common in men as in women It has been suggested that the causal agent, *Hemophilus ducreyi*, may be carried in the vagina without producing symptoms or ulcerations. It is transmitted by sexual intercourse However, infections may occur through contaminated towels and instruments, uncleanliness, and vaginal or urethral discharges In women chancroids occasionally occur round the vestibule, on the labia and occasionally on anal tags

The incubation period is up to 5 days, at the end of which a small reddish macule appears on the genitalia which soon becomes a pustule This ruptures to form a circumscribed ulcer with sharply defined, irregular, undermined edges and a gray, necrotic base The ulcers are multiple, as a rule, extend peripherally, and coalesce to form large, irregular ulcers with surrounding inflammatory areolae, which are circular or oval, rather soft and covered with an abundant, purulent secretion. These ulcers are extremely painful and tender The inguinal lymph nodes are swollen and tender and are termed *buboes*.

The diagnosis of uncomplicated chancroid is based on the identification of *Hemophilus ducreyi* on smear from a characteristic ulcerative lesion, a positive reaction to Ducrey vaccine, absence of *Treponema pallidum* on darkfield examination and negative Wassermann and Frei reactions. Failure to demonstrate Ducrey bacilli on smear does not necessarily rule out the disease. In lesions which are contaminated or treated with caustics, or of long duration, with sloughing areas, it is difficult to obtain the organism

Reaction to Intradermal Injection of Ducrey Vaccine. The reaction following the intradermal injection of 0 1 ml of Ducrey vaccine is specific At the end of 48 hours a papule 10 mm in diameter, surrounded by a zone of erythema 5 mm wide, denotes a positive reaction. A negative reaction leaves little to be seen at the site of inoculation The reaction becomes positive between 8 and 15 days after the appearance of the local lesion. A negative reaction after this time rules out a chancroidal infection in about 95 per cent of cases. A positive reaction may mean that the patient has a chancroidal lesion at the time the test is performed or that he has had a chancroidal lesion at one time. The reaction probably remains positive throughout the patient's life,

The disease may yield to treatment with sulfonamides

Fibrosis of the Sheath of the Corpora Cavernosa (Peyronie's Disease). In men between the ages of 30 and 60 years fibrosis of the sheath of th

A slight degree of stricturing causes no symptoms and requires no attention unless the patient has a chronic urethritis such as occurs in gonorrhea In some instances a gonorrheal infection may not be necessary for the origination of the urethritis A simple urethritis, with discharge so profuse as to be mistaken for gonorrhea, may be due to a strictured meatus, not necessarily tightly strictured, and disappears on correction of the stricture. Some aging men who have symptoms similar to those resulting from a large prostate gland are relieved by meatotomy.

Small strictures may interfere enough with the discharge of urine finally to injure the kidneys sufficiently to cause renal insufficiency, which may become manifest at any age, sometimes in youth, sometimes not until old age

Strictures of the posterior urethra of congenital origin are often caused by valve-like structures which have definite relationship to the superior or the inferior crista of the verumontanum. The symptoms appear in infancy, in childhood or in early adult life The stream is dribbling and the bladder distended when retention is great, but when the retention is slight, the bladder is not distended and the symptoms may be obscure. As the result of the retention of urine, soon there is an infection of the upper part of the urinary tract and perhaps finally renal insufficiency

The patient often has lost weight and is pale There may be dribbling of urine as if enuresis were present Patients who have had symptoms for a long time may be dwarfed and infantile, as is observed in so-called renal rickets.

There is no interference to the passage of a catheter, which usually reveals the presence of residual urine An intravenous urogram discloses the impairment of renal function and the dilatation of the upper urinary organs. If renal function is impaired, an hour or two must elapse before a satisfactory film can be obtained. The valve is identified through a urethroscope. It may sometimes be seen by cystoscope

Epispadias is rare The urethra lies ectopic as a groove for varying distances along the top of the corpora cavernosa. The penis is wide and short The urethra of the exstrophied bladder is epispadic and the epispadic urethra without exstrophy is usually incontinent

Hypospadias situated in the balanic or penile urethra is but an arrest of the closure of the urethra in these segments. There are varying degrees of lack of closure, however, and thus these malformations range all the way from pseudohermaphroditism to simple hypospadias.

The urethra opens at the frenum or just back of it in balanic hypospadias, and on the underside of the shaft of the penis in penile hypospadias. In penoscrotal or perineoscrotal hypospadias the urethra opens on the anterior or posterior face of the scrotum but always beyond the sphincters. The urethral opening is often deformed and is congenitally strictured

The penis beyond the urethral opening is deformed The glans is wide and split, as it were, by the failure of the floor of the urethra to unite. This broad glans is tilted downward as though pulled over by the shortened urethra Its undersurface is often marked by an indentation or a little pocket at the site of the lacuna magna The congenitally split prepuce, divided on the ventral surface, is piled up on the dorsum in irregular folds.

The tight meatus may cause urinary frequency or infection, but the essential

scrotal hypospadiac

Nonspecific Urethritis. Inflammations of the urethra may be (1) bacterial, (2) parasitic, (3) traumatic or (4) irritative. A distinctive difference between nongonorrheal urethritis and gonorrheal urethritis is that gonorrheal urethritis begins at the meatus, whereas all other urethral infections generally originate in the prostate.

deep pelvic chain of lymphatic structures is involved and that whatever treatment is considered is likely to be only palliative.

Amputation should be done in all cases, for if metastasis is not present, amputation will cure the condition and if it is present, the procedure will get rid of a badly infected, odorous, primary tumor

THE MALE URETHRA

(*Urethra Virilis*)

The male urethra varies greatly in length, and therefore only average measurements can be given In the adult its length is about 8 inches (20.3 cm); of this, 1¼ inches (3 2 cm.) is prostatic, ⅕ inch (0.5 cm.) being in the bladder wall; ⅖ inch (1 cm.) is mebranous, a little more than 6 inches (15 2 cm.) is penile Its caliber varies, being smaller at the meatus and in the membranous portion than elsewhere The meatus admits a No 24 French sound (often larger), the membranous portion a No. 26 to a No 28. The prostatic portion is the largest, admitting a No. 32 sound The bulbous portion is almost as large, admitting a No 30 to a No. 32. Therefore a sound which passes the meatus should find no further obstruction. The fossa navicularis just beyond the meatus is larger than the rest of the urethra.

If urine begins to flow when a catheter is introduced about 8 inches (20.3 cm), it is safe to assume that the urethra is of normal length. If the bladder is distended, as soon as the catheter passes the membranous portion, about 6¾ inches (17 2 cm) from the meatus, urine may flow. In hypertrophy of the prostate the prostatic urethra is much increased in length and it may require a catheter 10 to 12 inches (25.4 to 30 5 cm) long to draw urine If a sound is stopped by a stricture less than 6 inches (15 2 cm.) from the meatus, it is anterior to the triangular ligament. The stricture is termed an *anterior stricture* Strictures where the subpubic curve is lowest, that is, in the bulbomembranous region, are termed *posterior deep strictures*, which are the commonest form Strictures of the prostatic portion of the urethra are almost unknown.

The urethra contains small mucous glands (glands of Littre) opening on its surface, and small pockets or recesses, called the *lacunae of Morgagni* The glands of Cowper open into the bulbous urethra just in front of the triangular ligament The racemose glands of the prostate open into the sides of the floor of the prostatic urethra, and the ejaculatory ducts open near the middle line just in front of the urethral crest (verumontanum)

Urethral Muscles. There are two sets of muscles in connection with the urethra; one set might be said to aid in expelling the urine, and the other, in retaining it. The expulsors are the longitudinal and circular fibers surrounding the urethra just outside the mucous membrane and the accelerator urinae or *bulbocavernosus* muscle The sphincters are the *compressor urethrae* or *external sphincter* muscle, and the internal sphincter at the neck of the bladder

Malformations. Important malformations of the male urethra and its accessory glands are of rare occurrence and consequently not all of them will be discussed

Absence of urethra is associated with absence of penis and also may exist when the penis is present There is complete retention of urine, and the infant dies unless the bladder drains through urachus or bowel Death usually ensues within a week or 10 days *Atresia* occurs either at the meatus or at the prostatic urethra. The condition is usually fatal if some arrangement cannot be made to get rid of the urine

Congenital stricture at the meatus may be only a slight narrowing of the orifice due to a fold of mucosa that elevates the floor of the canal. Such a constriction is of no significance unless the patient contracts gonorrhea or until instrumentation becomes necessary. The stricture may be so small that only the finest probe will enter. The narrowing may be at the meatus or at the inner end of the fossa navicularis or both.

Good evidence does not exist of any degree of natural immunity to gonococcal infection. The girl child is the most susceptible If any degree of acquired immunity exists, it is not measurable. There is no infection immunity such as exists in tuberculosis and syphilis That is, fresh infections may be superimposed on more chronic ones. One attack of the disease does not protect from future reinfection.

The incubation period of gonorrhea varies from 2 to 7 days. The most accurate information concerning the incubation period of this disease has been obtained from experimental inoculations. Under these conditions the urethritis is evident within 2 to 5 days.

Acute Gonorrheal Urethritis. The initial symptoms of an acute gonorrheal infection are those of acute anterior urethritis. There are a teasing sensation, a mucopurulent discharge and slight inflammatory swelling of the lips of the meatus. In from 1 to 3 days the meatus becomes swollen, the discharge thick, profuse and purulent, and urination and erections are at least uncomfortable and perhaps painful.

The inflammation of the urethra with a *second attack of gonorrhea may be so* mild that it scarcely invades the submucosa. The discharge is mild, erections are not *painful If the infection is unusually intense, hematuria may occur as* well as urethrorrhagia from bleeding of the anterior urethra.

Examination reveals mucopurulent urethral discharge. The diagnosis is established by positive smear and culture for the gonococci.

The complications of acute urethritis are abscess of the anterior urethral glands, periurethral abscess, cowperitis, spongiitis and cavernitis, balanoposthitis and lymphangitis and lymphadenitis These complications can rarely be separately identified clinically since small abscesses occur as the result of obstruction of crypts and glands, as a part of the acute infection, and are important in the production of the symptoms of the disease. The most frequent form of periurethral abscess is the frenal abscess It scarcely ever abates without suppuration, often requiring incision After incision it may continue indefinitely to discharge a secretion containing gonococci.

The less frequently occurring complications may be enumerated: (1) Periurethritis along the pendulous urethra occurs as small, hard nodular points of tenderness Introduction of a sound may be necessary in order to palpate them. These points, too, harbor the gonococci (2) Abscess of Cowper's gland is not recognized until the abscess has burrowed along the perineal fascia and its reflection and presents itself at the penoscrotal angle, where it bursts or is incised The original focus can be diagnosed by finding that the cavity runs back to the membranous urethra and not to the prostate (3) Inflammation of the erectile tissues, other than the brief pains of chordee, is rare (4) A lymphadenitis originating from secondary infection from other pyogenic organisms is frequent and in rare instances causes suppuration

The diagnosis is made by stained smears which are microscopically studied for the presence of intracellular gram-negative cocci.

There is evidence of a gonococcal complement fixation antibody which is acquired slowly after the onset of the infection The complement fixation test in gonococcal disease has not attained general acceptance.

Acute Posterior Urethritis and Prostatitis. Posterior urethritis and prostatitis are always a part of an acute gonorrheal urethritis As the infection varies in degrees of severity, so do the manifestations of its *urethral distribution vary.*

The symptoms of posterior urethritis and prostatitis are frequent, urgent and painful urination with terminal hematuria There is pus in the "second" or residual urine. The pain of the second infection or the first mild infection is no more than an itching sensation referred to the end of the urethra. Posterior urethritis with a first severe attack of gonorrhea is likely to be intense As the muscles contract to expel the last drops of urine, the resultant pain is often a series of spasms that may

The types of *bacterial urethritis* are (1) gonorrheal, (2) urethritis due to an indwelling catheter which disappears when the catheter is withdrawn, though a mild prostatitis is likely to persist; (3) urethritis by extension of pyogenic or tuberculous infection originating in the prostate, and (4) metastatic urethritis occurring in a canal damaged by previous inflammation. Spontaneous severe urethritis may develop when uncontrolled diabetes exists.

Parasitic urethritis may occasionally be caused by trichomonas. Trichomonas infections are common in the male urethra. Feo found 144 infected men in a group of 926. Separating this group into white and Negro men, the percentage incidence was 12 and 16.5 respectively. Of the 926 men examined, 246 were classed as having nonspecific urethritis. However, in all of these the urethritis was not due to trichomonas. The percentage incidence of nonspecific urethritis which may be attributable to *Trichomonas vaginalis* was 36 9. The entire group of *Trichomonas vaginalis* positive men was relatively free from symptoms. A discharge may be noted which is characteristically small in amount, thin in consistency and of a dirty white color. Microscopically this discharge shows a few epithelial cells and a moderate number of pus cells and trichomonads. Some of the stained smears were similar to vaginal ones from cases of *Trichomonas vaginalis* vaginitis as to number of trichomonads and types of bacteria. The male is the important transmitter of *Trichomonas vaginalis* infection, while the female eventually becomes a reservoir of infection

Traumatic urethritis is due to rough passage of instruments, urethral stone, foreign body or cauterizing injections The more serious and complete stricturing of the urethra is often due to trauma as the result of external violence

Irritative urethritis is due to the excretion of irritating substances in the urine, for example, cantharides, turpentine, arsenic and potassium iodide Irritation from urethral instillations of caustic substances, such as silver nitrate solutions, may be severe and serious.

The symptom of nongonorrheal urethritis is a discharge of pus from the meatus. This symptom is mild and inconsequential as compared to the syndrome of acute gonorrhea In diagnosis the absence of gonococci must be proved by urethral culture on the proper media

Posterior Urethritis. The lesions of chronic posterior urethritis are (1) diffuse inflammations, (2) granulomas, (3) cysts, (4) deformities due to operation or to rupture and scarring of a prostatic abscess and (5) verumontanitis and utriculitis.

The symptoms of chronic posterior urethritis are often mild and manifested by a lack of erection, premature ejaculation, painful ejaculation, and pain in the perineum, in a testicle or in the sacrum. These symptoms are like those often attributed to verumontanitis, for instance, absence of ejaculation, painful ejaculation, discomfort of various types in the perineum, and various reflex pains.

The diagnosis is established by endoscopic examination.

Urethral Gonorrhea. Urethral gonorrhea is caused by the gonococcus, which belongs to the family Neisseriaceae, genus *Neisseria. Neisseria gonorrhoeae* is a gram-negative coccus which is the type species To the same family and genus belong also the meningococcus and several nonpathogenic inhabitants of mucous membrane

Neisseria gonorrhoeae is the causative agent of gonorrhea and of ophthalmia neonatorum. The organisms appear in the exudate of acute gonorrhea as diplococci, flattened or slightly concave and crowded together in pairs.

Gonorrheal infection occurs spontaneously only in man. The gonococcus causes infection of the genitalia and the genital tract generally, and may give rise to conjunctivitis, cystitis, proctitis, hepatitis and stomatitis The septicemic manifestations ... con- ... and

may progress to complete pathologic amputation of the penis. This too is rare and the diagnosis is not made

Stricture. As chronic urethritis heals, a scar is formed A stricture is the scar that results Strictures external to the bulbous urethra are termed *anterior* strictures. Those beyond this point are *posterior* or deep strictures. Strictures are classified as *inflammatory* and *traumatic.*

Inflammatory Strictures. Severe strictures result from gonorrhea or are complications thereof. Usually only mild strictures result from nongonorrheal inflammation

Strictures as the result of gonorrhea are more frequent after virulent infections than after mild infections For instance, the more intense the chordee, the more frequent and violent the relapses and the longer the gonococcus can be found in the discharge, the greater is the probability of strictures

Inflammatory stricture may result from scarring about the obstructed and chronically inflamed glands or lacunae. The overdilatation of a stricture may be followed by a more severe stricture Suppuration may follow overdilatation or may occur spontaneously. The direction that a suppurative process takes is determined by the fascia. If a prostatic abscess bursts backward, or suppuration following overdistention occurs in the same place and does not drain forward into the urethra, the pus either reaches the ischiorectal fossa and appears at the surface in front of or alongside of the anus, or is confined by the fascia

The following enumeration lists other suppurative processes which complicate stricture. (1) The suppuration of prostatic abscess, especially if due to tuberculosis, often reaches the surface in the perineum or may extend forward to the scrotum and up into the groin between the penis and the spermatic cord. Thence it spreads upward and outward toward the loin, beneath the deep layer of the superficial fascia (2) Suppuration in Cowper's gland extends forward and passes along the urethra to the penoscrotal angle and surface of the scrotum (3) Suppuration from the bulbous urethra usually breaks directly into the perineum, whence it extends to the ischiorectal fossa, scrotum, groin, pubes or anterior abdominal wall. (4) Suppuration from the penile urethra bursts directly through the skin of the penis. (5) Inflammation and dilatation of the bladder, the ureters and the kidneys are late results of strictures A stricture unaccompanied by sclerosis or spasm of the vesical neck does not cause partial retention of urine Stone in the bladder is rarely the result of stricture

Traumatic Strictures. The penile portion of the urethra may be cut, torn, or broken by external violence A crushing force applied to the perineum causes a stricture at the bulbomembranous junction by bringing the urethra sharply into contact with the undersurface of the pubis, crushing it beneath the sharp edge of this structure Falling astride a fence or a fence post may cause a traumatic stricture in the posterior portion of the urethra These injuries to the urethra may be overlooked by the patient if they do not give rise to immediate hemorrhage or urinary retention The prostatic urethra becomes strictured when torn by disruption of the pelvis Trauma originating from within, such as ulceration from stone, foreign body or retained catheter, or injury by the sharp point of an instrument, usually affects the bulbomembranous junction of the urethra Stricture at the neck of the bladder results from chronic prostatitis and transurethral resection of the prostate.

Within one year after a severe inflammatory process or trauma most patients will have strictures with manifest symptoms A few will show no symptoms until after 5 years In an occasional patient the onset may be deferred for 15 years or even longer Organic stricture may exist for years, producing no symptoms and entirely unsuspected by the patient

The initial symptom is usually the presence of pus and heavy thick shreds of pus in the urine. After stricture formation which immediately follows gonorrhea the urethral discharge does not cease.

last for a few minutes after urination or may continue in the tonic spasm of strangury during the short period between successive urinations In these patients urination is genuinely agonizing.

Toward the end of the acute period of gonorrhea (2 months) the patient, even if untreated with antibiotics or chemotherapy, has no symptom other than a drop of pus at the meatus when he awakes in the morning (the morning drop). This drop of pus may be so mucoid that it may stick the lips of the meatus together.

The diagnosis is established by positive smears and cultures

The complications of acute posterior gonococcal urethritis are prostatic abscess, vesiculitis, epididymitis, cystitis, and occasionally pyelonephritis and peritonitis.

The distinction between acute prostatitis in which miliary abscesses have not yet appeared and *prostatic abscess* cannot be made clinically. The gonococcic prostatic abscess and *vesiculitis* have no distinguishing features from any other etiologic types of these diseases When there is *epididymitis,* there is vesiculitis. The *cystitis* of gonorrhea is a trigonitis It is an extension of the mucosal inflammation of the posterior urethra A general cystitis may occur in gonorrhea if there is a retention of urine

A nongonococcal pyelonephritis may occur in the course of gonorrhea

Chronic Gonococcal Anterior Urethritis. When the disease lasts for more than 2 months, the gonococci diminish in number in the pockets in the urethral wall, to be replaced by other bacteria which keep up a mild inflammation. If stricturing and poor drainage prevail in a debilitated patient, anaerobic bacteria may cause periurethral gangrene

The most persistent form of chronic anterior gonococcal urethritis is caused by a frenal abscess. The urethra may become free from gonococci only to be reinfected from this source The course of a chronic gonococcal urethritis is often a series of exacerbations of the acute process Apparent improvement or cure is followed by exacerbation, seemingly caused by indiscretion, by reinfection of the surface of the urethra from an infected focus.

The diagnosis is established by positive smears and cultures

Chronic Gonococcal Posterior Urethritis. The clinician can rarely obtain a positive smear for gonococci from the prostate or the vesicles The bacteriologists, however, can often get positive cultures

The inflammation loses its characteristic irritability, and the urethritis tends to run a milder and more even course after the gonococci have disappeared Many of these patients have a posterior urethritis by secondary invaders Although some of these patients have not had gonorrhea, it is their lot to have an irritable prostate which has been treated for gonorrhea which they did not have.

Prognosis in Urethral Gonorrhea. The foregoing description of gonorrhea in the male is becoming out of date since the advent of chemotherapy and antibiotics (duracillin). The following prognosis applies to those who have not been thus treated.

The average man should recover from gonorrhea in 3 months if he has no complications such as stricture, prostatitis, epididymitis or vesiculitis If the infection is complicated by a frenal abscess, the course may be indefinite It is most unusual for the gonococcus to persist in the male Prior to use of antibiotics many patients recovered from gonorrhea without or despite treatment

Chronic gonorrhea in women may almost last indefinitely

Amicrobic Urethritis. In France there has been described an increased incidence of amicrobic urethritis in men that has proved resistant to penicillin and sulfonamide compounds. Harkness has insisted that this infection is caused by a *virus* This form of urethritis may be associated with prostatitis and epididymitis.

Syphilis. Chancre of the urethra as a rule is not recognized. Chancre has not been described in the deep urethra. Gumma occurs in the corpora ca[illegible]a and

tinence. Diverticula of the penile urethra may produce a swelling of the ventral portion of the penis when the patient voids.

Visualization of the urethra by cysto-urethrography is the best method of diagnosis. Radiopaque substances injected into the urethra clearly outline the diverticular sac.

Tumors. The neoplasms of the male urethra arise from the epithelium. Tumors arising from other elements, such as sarcomas, are rare.

Benign Tumors. Benign papillary tumors occur in any portion of the urethra but are commonest in the posterior portion. These tumors of the male urethra usually are small delicate neoplasms. Histologically they are composed of epithelial cells, mitotic figures are not present, and there is no evidence of invasion or other signs of malignancy. Initial hematuria is the most frequent evidence of urethral papilloma. Tumors situated in the posterior part of the urethra may cause sterility by occlusion of the ejaculatory ducts The diagnosis is established by endoscopic examination and biopsy.

Malignant Tumors. Carcinoma is the commonest primary malignant tumor of the male urethra This lesion occurs most often in men between 40 and 50 years of age.

Cancer may arise in any portion of the male urethra There has been no significant difference in its frequency in the anterior and the posterior portions of the urethra Histologically these tumors usually are epidermoid carcinoma or adenocarcinoma. Primary carcinoma of the urethra metastasizes late in the disease

Slow stream, frequency, dysuria and hematuria are symptoms of primary carcinoma of the urethra. Considerable infection seems to be a feature of these neoplasms, and abscess formation and fistulas are common.

Diagnosis is established by biopsy Early diagnosis of urethral carcinoma is difficult. Symptoms are so suggestive of stricture of the urethra that many patients with urethral cancer have been treated for stricture. Tumors of appreciable size can be felt along the urethra. Any progressive narrowing of the urinary stream associated with a palpable mass along the course of the urethra should suggest carcinoma.

THE SCROTUM

Anomalies. Anomalies of the scrotum include underdevelopment of the scrotal [illegible]

[illegible]
However, the scrotum is peculiarly resistant to infections.

[illegible]

in appearance. Gangrene appears and spreads rapidly and soon the skin sloughs away The process extends beneath Colles' fascia and may spread into the groins and onto the abdominal wall. The testicles are left exposed Even after extensive involvement the process ceases suddenly, as it commenced, granulation appears and the scrotal skin regenerates quickly.

Gangrene is differentiated from phlegmon by the absence of history of disease causing extravasation of urine Phlegmon does not slough extensively One of each 5 who have the disease dies

Elephantiasis. Elephantiasis of the scrotum is endemic in many southern regions The disease is due to infestation by a nematode worm, *Wuchereria bancrofti.*

The symptoms of filariasis are episodes of lymphangitis, lymphadenitis and swelling of the scrotum Repeated attacks of the disease may result in enormous scrotal enlargements Except for this deformity, the physical condition of the patient is unaffected.

Frequent micturition, often painful, is due to straining to overcome the urethral resistance, prostatitis and cystitis. If there is pyelonephritis, the frequent urination may be a true polyuria

If a stricture becomes congested, it closes, and acute retention of urine ensues. If this retention is unrelieved, the progression is like that of an acute prostatic retention from benign hypertrophy.

As the stricture contracts, the urethritis grows worse and, sooner or later, produces a morning discharge (gleet). The morning discharge gets better or worse according to the degree of acidity of the urine and the amount of sexual indulgence. As the stricture tightens, the stream of urine is small and irregular. Erection is sometimes imperfect and painful

The pain on urination in stricture is due to prostatitis, cystitis or retention. It is perceived deep in the urethra, in the perineum, at the point of stricture, or near the glans penis

When gross hematuria occurs, it is often the only symptom of stricture noticed by the patient. The bleeding comes from a shallow ulcer and may be profuse The blood usually continues to drip after the close of micturition (urethrorrhagia).

DIAGNOSIS The diagnosis of strictures is made only by those trained to use the bougie and the sound (1) In stricture of the pendulous or scrotal urethra the bulbous bougie either fails to pass the strictured point or passes with a jump and is caught again by the stricture on withdrawal. (2) Stricture at the bulb is diagnosed by use of a sound A sound distinguishes stricture from spasm by the fact that, when it has entered the stricture, it is grasped on withdrawal. Blood follows withdrawal of the sound (3) Spasmodic stricture is a symptom, not a disease. It is a subjective spasm, created by an unduly irritable muscle because of urethritis or prostatitis Urethral spasm is often a postoperative complication (4) Traumatic strictures contract rapidly and are usually incurable The more extensive a stricture, the more irregular its surface, and the denser the cicatricial tissue composing it, the more difficult will be its treatment and the more dubious its cure.

If death results from a stricture, it is from septicemia, obstruction of urine and renal failure, or periurethral gangrene When the patient is debilitated, sudden death may occur after the passage of a sound.

Urethral Stones. Vesical calculi may pass into the urethra and become impacted along its course. Prostatic calculi occasionally erode through the mucosa and obstruct the urethra Primary urethral calculi may form behind a stricture or within a diverticulum Urethral calculi cause varying degrees of obstruction, depending on their size

Patients who have urethral calculi often are unaware of the presence of the stones The diagnosis frequently is made by the passage of some instrument into the urethra Characteristic grating then may be felt This sensation may be obtained at times when tough old strictures of the urethra exist so that stone is suspected although not present. Stones within urethral diverticula are detected by roentgenologic examination

Diverticula. Diverticula of the male urethra are uncommon They are classified as congenital and acquired.

Congenital Diverticula. Diverticula of this type are said to occur most often on the floor of the penile portion of the urethra Their origin is thought to be due to incomplete fusion of that portion of the urethra which is derived from the phallic part of the genital tubercle with the portion of the urethra which is derived from the urogenital sinus.

Acquired Diverticula. The acquired types of urethral diverticula are due to the presence of stricture or stone, abscess formation or trauma The symptoms if present are those of chronic inflammation: dysuria, dribbling and incon-

The testis is covered by peritoneum, which is prolonged at its upper and lower ends The lower end reaches down to the internal ring and later contains fibrous and muscular tissue and passes through the inguinal canal to the lower part of the scrotum; it is called the gubernaculum testis It reaches its highest development in the sixth month, and its remains attach the testicle to the lower part of the scrotum as the ligament of the scrotum As the testicle descends, it is preceded in its descent through the inguinal canal by a fold of peritoneum, the vaginal process, which forms the tunica vaginalis over the testicle

The vaginal process may not entirely close, so that the peritoneal fluid passes down to the tunica vaginalis covering the testicle; this is called a *congenital hydrocele.* If the opening is large enough for intestine to enter, it forms a *congenital hernia.* If the opening is closed above, usually at the external ring, and fluid accumulates in the tunica vaginalis, it forms an *infantile hydrocele.* If a portion of the vaginal process persists somewhere along the spermatic cord between the internal ring and top of the testis, there is an *encysted hydrocele.* A hydrocele in the inguinal canal of the female is a hydrocele of the canal of Nuck.

Anomalies of the Testicles. *Anorchism* or *monorchism* is extremely rare unless there is in addition an absence of one or more of the other elements of the seminal tract The failure to find an undescended testicle on surgical exploration is not prima facie evidence of its congenital absence Likewise *synorchism* is not a good explanation for not finding the second testicle.

Polyorchism is rare, but when present, there is but one vas and the duplicated testicles are joined by the epididymis

The absence of one testicle is rare, but when one testicle is lacking, there is absence of the homolateral kidney also, for there is absence of the whole urogenital fold

In *cryptorchism* the ectopic testicle may be halted at any point of its normal descent. It may be situated anywhere throughout the length of the inguinal canal. In infancy retention in the canal is common Retention frequently occurs at the external inguinal ring, in the groin and in the proximal portion of the scrotum.

The ectopic testicle becomes sterile because of the slightly higher temperature of its bed in the groin or inguinal canal than of the normal situation in the thin-walled scrotum Puberty is the accepted dividing line in determination of normal development of the testicle. It is expected that placement of the testicle in the scrotum before puberty will result in normal testicular development in size and function Retention of the testicle above the external inguinal ring after puberty is accepted as proof that the testicle has failed to attain normal size and spermatogenic function

When both testicles are ectopic, there is no spermatogenic function, although the hormones that determine the development of the secondary sexual characteristics and preside over the growth of the prostate and seminal vesicles are produced in undiminished quantities The secondary characteristics of sex develop normally.

The undescended testicle is much more liable to malignant growth than the normally situated testicle In almost every instance, if the testicle does not descend, there is a congenital *hernial sac* above the ectopic testicle

Infections of the Testicles. Direct extension of inflammation from the epididymis accounts for most instances of local inflammatory disease of the testicles. Blood-borne infections of the testis occur in pyogenic generalized infections· mumps, syphilis, the rickettsial fevers and typhoid fever.

Epididymo-orchitis occurs as a complication of injuries and operations on the bladder and prostate. In severe epididymo-orchitis the substance of the testis is destroyed by acute inflammation and abscess formation The swollen scrotal contents cause considerable pain and discomfort The cord is enlarged and tender along its course, giving pain and tenderness in the lower part of the abdomen suggestive, at times, of acute appendicitis As the scrotal mass increases in size, it first is hard and then becomes fluctuant Acute, severe epididymo-orchitis is obvious

Lymphedema. Progressive lymphedema of the extremities and scrotum occurs among men who never have resided in the tropics. This condition is the result of obstruction of the lymph channels and like Milroy's disease of young women may be congenital in origin Rarely is there a history of any significant infection or injury

Tumors. New growths of the scrotum are not common.

Benign Tumors. The benign tumors may be enumerated: (1) Vascular neoplasms and an occasional accessory spleen in the scrotum are recorded as examples of tumors of congenital origin. (2) Sebaceous cysts are common. They appear as yellowish, round, freely movable tumors which vary in size and number The cysts are filled with thick, foul debris Usually scrotal cysts require no treatment. (3) Lipomas are composed of large lobules of well-encapsulated fatty tissue. Symptoms result only from weight and pressure (4) Connective tissue tumors of the scrotum are slowly growing, small hard neoplasms. (5) Myxomas of the scrotum occur as smooth, lobulated masses and may attain considerable size These neoplasms are said to transilluminate (6) Tumors of the lymphatic vessels occur as diffuse lesions The skin is edematous, indurated and often ulcerated These neoplasms are occasionally malignant (7) Hemangiomas originating in the subcutaneous tissues, may slowly enlarge. They are composed of masses of dilated blood vessels filled with blood.

Malignant Tumors. Most malignant tumors of the scrotum are epitheliomas

CARCINOMA OR EPITHELIOMA. Considerable interest is attached to carcinoma of the scrotum because of its rapid growth, high mortality and occupational incidence This was the first recognized occupational cancer.

Carcinoma of the scrotum may develop in workers in certain industries as a result of their occupation Chiefly these are chimney sweeps, employees in textile industries, and men exposed to tar, pitch and lubricating oils *Mule spinner's disease* is cancer of the scrotum occurring in men who work in the cotton industry where they are exposed to the carcinogenic agent present in mineral oil used for lubrication This disease has nothing to do with the faithful farm animal, the southern mule.

Carcinoma or epithelioma of the scrotum is epidermoid carcinoma The lesion starts as a small wart, which soon ulcerates The ulcer is hard and indurated and has everted edges. As the lesion advances, the lymph nodes of the groins become involved and are felt as hard, tender masses which also eventually ulcerate

Scrotal cancer metastasizes to the inguinal and femoral lymph nodes Crossed metastasis occurs frequently.

The diagnosis is established by biopsy Scrotal carcinomas are highly malignant tumors Even with early excision the prognosis is not good.

SARCOMA Sarcoma of the scrotum is rare

THE TESTICLES AND ASSOCIATED STRUCTURES

The Testicles. *The normal testicles are 1½ inches (3 8 cm) long, 1 inch (2 5 cm) wide, and ⅘ inch (2 cm) thick* If larger, they are either hypertrophied or diseased. They are firm to the touch If hypertrophied, their consistency is not materially altered, if diseased, they are usually harder than normal. If smaller, they are usually atrophied and besides the lessening of size are also softer and flabby in consistency

The testicles rest attached at the inner posterior portion of the scrotum and the long axis points upward, slightly forward and outward In the presence of hernia and hydrocele the testicle is to be felt for first at the inner posterior aspect of the swelling. If not found here, the testicle may be palpated anteriorly instead of posteriorly. The position of the testicle in the presence of hernia or hydrocele can also be determined by seeing its outline by means of a light placed on the opposite side of the scrotum.

Descent of the Testicles. The testicles begin to develop early in fetal life, at about the third month, below and in front of the kidneys, opposite the second lumbar vertebra.

pathic hydrocele is a slow accumulation of fluid within the tunica vaginalis for no known reason. The soft tumor of the testicle transilluminates, and on needle puncture yields clear, straw-colored fluid.

Hydrocele must be differentiated from hernia. Hernia does not transilluminate, gives an impulse on coughing and often can be reduced. Spermatoceles contain milky fluid containing spermatozoa and usually are situated at the upper pole of the epididymis. Chronic hydroceles with thickened sacs, if large and uncomfortable, may require excision

Neuralgia. True neuralgia of the testicle or cord is an ache, constant and mild, which often is of long duration. The ache or pain may be situated throughout the length of the cord or in the testicle. The pain may be centered in the epididymis. In instances of severe pain of neuralgic nature in the testicle, removal of the testicles will not relieve the pain. The operation will make the neuralgia worse.

Prolonged sexual desire may produce neuralgia (*stoneache*).

Tumors of the Testicles. Tumors of the testicles are both benign and malignant

BENIGN TUMORS Hyperplasia of the interstitial cells of the testicles may occur in children This condition may be accompanied by precocious bodily and sexual development. Gynecomastia sometimes is present Adenomas, fibromas and hemangiomas have been reported but they are rare. Simple cysts of the testis are rare So-called benign teratomas have been described, but these tumors sometimes are malignant since they have been known to metastasize.

Benign tumors of the testis can be differentiated from malignant neoplasms only by microscopic examination.

MALIGNANT TUMORS Malignant tumors of the testis are often a most dangerous form of malignant disease

Malignant testicular neoplasms have been reported from birth to old age, but they are commonest between 20 and 45 years of age with an average age of about 35 years The association of malignant tumors with cryptorchidism is well established

Friedman and Moore found, on examination of 922 testicular neoplasms, that 96 per cent of these new growths fell into one of the following categories. (1) seminoma (germinoma), (2) (a) embryonal carcinoma and (b) chorio-epithelioma, (3) teratoma and (4) teratocarcinoma

The *seminoma* is one of the commonest of malignant testicular tumors. Seminomas have less malignant characteristics than embryonal carcinomas in that they tend less to invade and destroy adjacent tissues They occur at a later age than other testicular neoplasms *Embryonal carcinomas* fortunately are less common than seminomas *Chorio-epitheliomas* of the testis are rare. These are small, soft, hemorrhagic tumors They grow very rapidly and have a poor prognosis Characteristic of chorio-epitheliomas are their rapid growth, early wide dissemination, lack of radiosensitivity and high titer of chorionic gonadotrophin in the urine Most of these tumors end fatally within a short time

Teratomas are bizarre neoplasms which contain differentiated adult structures such as bone, cartilage or well-formed organs resembling teeth and hair. Any organ of the body may be represented in these tumors. They are slowly growing neoplasms which constitute fewer than 1 of each 10 new growths of the testicles. *Teratocarcinoma* or embryonal adenocarcinoma usually consists of a mixture of teratoid elements in the rete testis, but the epithelial elements grow rapidly and soon overgrow the tissue of origin It is a highly malignant tumor

ENDOCRINE TUMORS OF THE TESTES. In this discussion it is convenient to consider that a testicular tumor may arise from any one of the four different cellular structures. (1) the supporting connective tissue, (2) the interstitial cells of Leydig, (3) the supporting cells of Sertoli and (4) the germ cells. Tumors arising from cellular structures other than the germ cells are scarce. Three in every 100 testicular

ORCHITIS IN MUMPS. Orchitis in mumps rarely occurs before puberty. After puberty it occurs in about 1 of every 5 who have the mumps Severe orchitis is followed by atrophy of the testis in about one half of the cases.

Orchitis in mumps appears within 3 or 4 days to 1 or 2 weeks after the onset of the parotid swelling The involved testicle or testicles are swollen, firm and very tender. Epididymitis of mumps may occur alone without orchitis or parotitis and in some instances with very little parotid enlargement.

Orchitis in mumps after puberty is a serious condition, for testicular atrophy and sterility may ensue if both testicles are affected.

SYPHILIS *Testicular involvement* is an early and a constant consequence of syphilis Two forms of *syphilis of the testicle are described, either a sclerotic or a* sclerogummatous lesion may be present.

Bilateral sclerotic orchitis is characteristic of late syphilis. The only symptom present is diminution or loss of testicular sensation.

Sclerogummatous syphilitic orchitis tends to localize in the rete and to extend thence to the epididymis and adjacent tunica vaginalis The gumma may be palpated as an irregular, insensitive mass on top of the testicle with a hard ridge along one side The opposite testicle is insensitive to pressure.

The forementioned findings of a testicular mass, with the opposite testicle in*sensitive, and the history of syphilis in the presence of positive serologic reactions,* are diagnostic

Torsion. The cause of torsion is often unknown to the patient If torsion is more than one half of a revolution and if it is not promptly untwisted, gangrene of the testicle and epididymis ensue.

Torsion may occur in infants, but in most instances, perhaps 3 out of 4, it occurs between the ages of 15 and 25 years; in the remainder it occurs in adult life. It is usually situated on the right side

Slight torsion may recur a number of times before the circulation is sufficiently injured to cause atrophy of the testicle The onset of the pain may be mild or severe. Often attacks of mild pain and swelling of the testicle occur and subside, to be followed by more attacks, thus simulating epididymitis of gonorrhea or recurring trauma

In severe torsion the gangrenous testicle within a few days reaches an enormous size and its sensibility diminishes, but pain and fever persist.

The diagnosis of complete torsion of the cord is established by the history and examination Mild torsion may not be recognized before it becomes complete *If mild torsion is diagnosed, the scrotum should be incised and the testicle* sutured to the scrotum Had the gubernaculum of the testes anchored the testicle tightly to the bottom of the scrotum torsion would not have occurred

Injuries of the Testicles. The testicles are protected against injury by their mobility and position Injuries occur from *direct blows and lacerations.* Causes of injury may be enumerated as follows. (1) Exposure to roentgen rays may seriously affect the spermatogenic elements of the testis. (2) Contusions of the testis result from direct blows. These injuries cause severe pain because of edema and regions of hemorrhage within the organ. Contusions of the organ may result in hydrocele, *hematocele and sterility* Piercing wounds of the testicle are often serious and are followed by hemorrhage (3) Lacerations of the testis may occur from penetrating wounds of the scrotum Lacerations require suture of the tunica albuginea to prevent herniation of the testicular tubules.

Severe injuries of the testicle are accompanied by shock Pain is severe The scrotum becomes enlarged and discolored.

l within the tunica vaginalis occurs as an *acute*
ele results from trauma, inflammation such as
es from testicular neoplasms. Chronic or idio-

has been the subject of considerable comment. Confusion regarding the value of these tests arises when it is not recognized that the hormone present in the urine in those who have testicular tumors is different from the hormone present in castrates and in women past the menopause. The presence of chorionic gonadotropic hormone in the urine of a patient who has a possible malignant tumor of the testicle is an evidence of the presence of a tumor containing chorionic tissue A decrease in the chorionic gonadotropic hormone means removal or regression of chorionic tumor tissue An increase means a spread of the disease or an increase of follicle-stimulating hormone with a synergistic effect on the chorionic gonadotropic hormone.

Since the reactions to the Aschheim-Zondek and Friedman tests often are negative in seminoma and other tumors of high malignancy, the value of these tests in diagnosis is limited. However, the presence of chorionic gonadotropic hormone in the urine means that there is an active tumor somewhere and suggests a bad prognosis. The amount of gonadotrophin present in the urine is significant. Patients whose urine contains 2,500 or more mouse units per liter are short-lived All of those who have 10,000 mouse units in the urine have been proved to have chorio-epithelioma.

Most teratomas (adult teratomas) without malignant elements are cured by orchiectomy alone Seminomas respond well to orchiectomy and external radiation and many of these tumors probably are cured. Embryonal carcinomas and terato-carcinomas have a higher mortality rate, and in these neoplasms radical surgical intervention may produce better results Chorio-epithelioma, generally, gives a poor prognosis although an occasional patient with this neoplasm has survived for a number of years

The ten-year survival rate for treated patients who had seminoma, as reported by Cabot and Berkson, was nearly 50 per cent as compared with a ten-year survival rate of about 25 per cent for patients with other forms of carcinoma

Tumors of the Testicular Tunics and Spermatic Cord. The majority of the tumors of the testicular tunics are of mesoblastic origin and are lipomas, myxomas, fibromas, or mixtures of cell elements. Sarcomas occasionally occur. All of these are rare tumors

Most tumors of the *tunica vaginalis* are benign A few epithelial tumors have been reported, all benign adenomas. Other benign neoplasms are lipomas, fibromas and myomas All the malignant tumors have been sarcomas The *tunica albuginea* gives rise to fibromas or sarcomas.

Tumors arising from the testicular tunics usually resemble testicular neoplasms and are treated as such A few benign growths have been removed by local excision

Tumors originating from the *spermatic cord* are all mesoblastic and usually benign The commonest tumor of the cord is the lipoma

The Spermatic Cord. The left spermatic cord is longer than the right, hence the left testicle hangs lower The cord is composed of the vas deferens with its artery and veins, the spermatic artery with its veins, the cremasteric artery, and the layers derived from the abdominal wall which extend to become the tunics of the testicle The vas deferens is a small, round, hard cord lying posteriorly which is palpable through the scrotum.

Varicocele. Varicocele is varicosity of the veins of the pampiniform plexus of the spermatic cord *Spontaneous varicocele*, a mild form of varicocele, is a common affection It occurs usually on the left side. The deformity makes itself manifest before the age of 25 years A *symptomatic varicocele* may occur as the result of pressure on the spermatic vein on either side or on both sides

Some patients with varicocele have hypochondriac complaints. Old men do not complain of varicocele Perhaps there is a slight dragging sensation in the groin On examination the vessels are dilated and feel like a soft tangled cord or a bundle of worms

tumors studied by Friedman and Moore were germ cell tumors. Of the germinal cell tumors, *those arising from the Leydig and Sertoli cells are rare,* but their clinical manifestations are complex, for the Leydig extratubular cells produce androgen and the Sertoli intratubular cells produce estrogen. Therefore a condition is originated in which a masculinizing and a feminizing hormone are being produced side by side in the same gland. If the Leydig cell secretion, androgen, is excessive during youth, a giant is the consequence. If the Sertoli cell secretion is increased, the youth is feminine in character

The chorionic cell tumors produce a luteinizing type of gonadotrophin If gonadotrophins are produced in excess, estrogen also is produced in excess and *gynecomastia ensues. It is said that* any male who has enlarged breasts suffers from an endocrine imbalance This may be true, but often gynecomastia is present in youth without evidence of endocrine imbalance (see Diseases of the Breast, Chapter 8). Gynecomastia may be associated with disturbed testicular function observed after trauma, cryptorchidism, senility, severe hepatic damage and the administration of stilbestrol.

The excess estrogen in those who have chorio-epithelioma of the testes is formed in the tumor itself and can be extracted from it. The extract (gonadotrophin) from chorio-epithelioma of the testis gives a biologic test similar to that of the pregnancy-urine test *It is the amount of gonadotrophin present in the urine which is* significant. Large amounts (10,000 to 100,000 or more units) may be present in the urine from one who has a chorio-epithelioma. The amount of gonadotrophins present is indicative of the mass of functional tumor cells present.

Malignant tumors of the testis metastasize by lymphatic structures along the spermatic cord to para-aortic lymph nodes, then through the prevertebral chain of lymph nodes through the mediastinum and along the thoracic duct to the left supraclavicular fossa and perhaps to the lung. Metastasis to the left supraclavicular lymph node is present in an occasional case. Crossed metastasis, at a high level, may occur. *Inguinal lymph-node involvement occurs when the tumor has involved* the scrotal tissue The size of the primary tumor has little to do with the onset of metastasis

Despite the ready accessibility of the organ, symptoms of tumor of the testis frequently are not noticed for a long time Large masses may cause dull, dragging discomfort The presence of an abdominal mass or backache, from involvement of retroperitoneal lymph nodes, may be the first symptom of testicular tumor. Some tumors have an onset resembling acute epididymitis. In many instances trauma brings the tumor to the patient's attention Often the first manifestation of these new *growths is a metastatic lesion found on routine physical examination,* or the presence of a metastatic nodule in a lung revealed by roentgenographic examination, or an enlarged left supraclavicular lymph node Hydrocele may be found in association with testicular neoplasm Gynecomastia may be present

The diagnosis is made by biopsy after removal of the testicle for a tumor. Biopsy of the suspected testicle is never performed, since this procedure is likely to spread tumor cells and lead to local recurrence. If it is strongly suspected that a malignant testicular neoplasm is present, the entire organ, with its tunics intact, is removed. Difficulties in the diagnosis of these tumors are many Testicular neoplasms have been mistaken *for hydrocele, hematocele, epididymitis,* orchitis and tuberculosis It

the mass feels heavy. If hydrocele is present, the fluid may be aspirated to provide better examination of the testicle The cord usually feels normal

The value of hormonal tests in the diagnosis of malignant testicular neoplasms

is made Orchiectomy should not be performed until treatment with antibiotics has been given a trial.

Tumors of the Epididymis. Primary tumors of the epididymis are rare. They are benign or malignant.

BENIGN TUMORS. *Spermatoceles* are common. They may reach several centimeters in size They contain a milky colored fluid and transilluminate. Almost half of the primary neoplasms of the epididymis, lipomas, adenomas, leiomyomas and angiomas, are said to be benign. Mesotheliomas are nonmalignant neoplasms primary in the epididymis

Benign tumors of the epididymis are small and cause no symptoms. The presence of these benign tumors is detected in the course of a physical examination. Only by histologic examination is the diagnosis established

MALIGNANT TUMORS These tumors are about equally divided in their origin from epithelium and mesothelium Pain and a solid mass are the manifestations of a primary malignant tumor of the epididymis The diagnosis is established by biopsy.

The Vas Deferens The vas deferens descends to the lower end of the testicle and, becoming much convoluted, forms the globus minor or tail; thence it ascends, forming the body, and finally at the top, receiving the efferent ducts, forms the globus major or head Between the body of the epididymis and testis is a pocket or depression called the digital fossa Attached to the upper end of the testis is a small flat body which is in front of the globus major Attached to the globus major itself is a small cystic pedunculated growth. Both of these masses are known as the hydatids of Morgagni, the former is the remains of the duct of Muller, the latter is derived from the wolffian body The vas deferens then ascends along the spermatic cord to the internal abdominal ring of the inguinal canal

When the vas deferens leaves the internal abdominal ring, it winds around the outer side of the deep epigastric artery and dips down over the brim of the pelvis 1½ to 2 inches (3 8 to 5 1 cm) posterior to the pubic spine It then runs downward and backward on the side of the pelvis In its pelvic course the vas deferens is not often the subject of clinical significance except in cases of undescended testis.

Deferentitis. Deferentitis is recognized clinically in both acute and chronic forms which often follow gonorrheal infections. Also both acute and chronic forms of tuberculous infections are observed

The *acute infection* may be recognized as a thickening of the seminal vesicle which is palpable at the external ring. Commonly deferentitis extends from a tuberculous epididymis backward up the vas deferens. Muscular trauma at the inguinal canal occasionally excites suppuration.

Chronic tuberculous deferentitis is an irregularly distributed lesion, palpably knobby, and usually most marked in the scrotal portion As in epididymitis, it is tender or insensitive in proportion to the acuteness of the infection

The Seminal Vesicles. The seminal vesicles are about 2 inches (5 1 cm) long and lie on the bladder above the prostate. When normal, they are not readily recognized by touch, but in disease they are easily felt

Anomalies. Anomalies of the vesicles are usually part of some general genital malformation When one of the vesicles is absent, the corresponding testicle may yet be present Extreme dilatation of the vesicles is probably always acquired

The ejaculatory ducts may empty into the ureters instead of on the edge of the prostatic utricle In a few cases they have been found to continue forward alongside of the urethra the whole length of that canal to the meatus.

Wounds. Operative wounds of the ejaculatory ducts are frequent. The patency of the ducts is imperiled by prostatectomy.

Cysts. A gradual dilatation results from inflammation of the vesicles until they become two or three times their normal size and even overlap in the median line Such dilatations have no clinical significance. In rare instances one seminal vesicle may become obstructed at its outlet and then it will enlarge and form a tumor about

Tumors. Tumors of the cord are rare A lipoma is about the only tumor of the cord. It is secondary to hernial lipoma, is usually small, and is present in an inguinal hernia.

The Epididymis. The epididymis may be absent or imperfectly formed Such abnormalities result in sterility if bilateral. Abnormal relationships between testis and epididymis occur in defects of the urogenital union as previously described

Epididymitis. Epididymitis occurs most frequently in young men who have urethritis and aged men who have infection which has followed instrumentation during the course of prostatism.

Epididymitis is classified as follows· (1) gonorrheal epididymitis, (2) metastatic or septicemic epididymitis, of which tuberculous epididymitis is an example, (3) epididymitis following instrumentation and (4) epididymitis from trauma, physical and perhaps sexual excesses.

Gonorrheal epididymitis is acute or, if mild at the onset, tends to become acute later. The least trauma excites to an acute relapse. This relapsing tendency is short-lived The relapses of epididymitis after intervals of months or years are not due to the gonococcus Suppuration in gonococcal epididymitis is common

Metastatic epididymitis arises from distant infections, as for instance infection of the upper air passages, particularly tuberculosis or an acute pyelonephritis or some other source. Epididymitis is usually due to *Escherichia coli* or to *Staphylococcus aureus*. The bacillary infection shows the same tendency to gross suppuration, to involvement of the testis and cord and to relapse, as the epididymitis of urinary disease. Staphylococcal infections show a tendency toward healing and less tendency to suppuration and to relapse unless originating from a septicemia

Testicular injury and an ensuing epididymitis may follow trauma to the testicle such as may be sustained from falling astride a fence or from injury incurred during horseback riding The symptoms and course depend on the severity of the trauma. Rarely is the testicle injured sufficiently to require its surgical removal.

Epididymitis from *sexual strain*, the colored man's "strain," is usually of gonorrheal origin.

SYMPTOMS Often the inflammation begins slowly but later flares into an acute attack. In still others it remains mild and localized to the distal portion of the epididymis.

The acutely inflamed epididymis swells within a few hours to several times its normal size The organ is exquisitely painful and tender, the pain extending to the sacrum and to the loin. The temperature rises to 103 to 104 F (39.4 to 40 C). Intense symptoms may continue for days until relieved by infiltration of the sheath, after which the suppuration burrows through the scrotal fasciae, reaches the skin, bursts and leaves a chronic fistula

EXAMINATION. The acutely inflamed epididymis is a swollen, edematous ridge surrounding the normal testis The epididymis may become a large tender mass There may be epididymitis, periepididymitis and deferentitis The deferential lesions may extend the whole length of the vas and may be most marked at the lower end of the vas or at the external inguinal ring.

DIAGNOSIS The physical findings and history are usually diagnostically definite Epididymitis is distinguishable from torsion by the fact that elevation eases the pain of epididymitis and accentuates that of torsion When a swollen epididymis is associated with prostatitis, the condition is usually epididymitis Tuberculous epididymitis can ordinarily be distinguished by the history and the associated lesions and by its slow chronic course and perhaps by suppuration However, the diagnosis often is not made until histologic study has been done. After any form of epididymitis the prospect of sterility (on the affected side) is great.

Sporotrichosis of the Epididymis. Sporotrichosis of the testis and epididymis may occur in the course of a cutaneous sporotrichosis, in which event the diagnosis

trarectal (seminal vesicular carcinoma) and rectal carcinoma is the mobility of the rectal mucosa over the mass

Diagnosis of primary carcinoma of the seminal vesicle can be established by biopsy and histologic study

THE PROSTATE GLAND

The normal prostate gland is 1¼ to 1½ inches (3.2 to 3.8 cm) wide, 1 to 1¼ inches (2.5 to 3.2 cm.) long, and 1¼ inches (3.2 cm) thick. A central depression on its rectal surface separates it into lateral lobes. The prostatic tissue is continued uninterruptedly across the median line in the form of a commissure Enlargement of this part

rare and probably not

Nocturnal Emissions. Nocturnal emissions, usually associated with dreams, occur in boys and in men Such an emission is simply the discharge of semen while asleep

The fears that boys and young men can build on this physical phenomenon may be excessive. The experienced adviser will not even suggest posterior urethroscopy to the patient who complains of only infrequent emissions until a thorough understanding is had of the psychologic aspects of the patient and an attempt has been made to establish an alleviation of fear and anxiety by exercise, cold baths and diversion in a normal and unmorbid society, to diminish the number of the emissions and to minimize their importance in the mind of the sufferer. If these measures fail, it may be necessary to have recourse to more formal psychic investigation and then to examine the posterior urethra

Nocturnal emissions may continue in aged men long after they have become impotent. Often it must be explained to these aging individuals that the occurrence of these emissions is a normal phenomenon and not the sign of latent virility.

Hemospermia (Bloody Ejaculatory Fluid). Hemospermia may be symptomatic or idiopathic in origin

Symptomatic hemospermia may arise from prostatitis or vesiculitis, prostatic concretions, tuberculosis, or carcinoma, or may be due to sexual excesses. Hemospermia and hematuria may occur simultaneously Symptomatic hemospermia is of no great interest, for this symptom alone cannot be evaluated and is thus termed idiopathic hemospermia

Idiopathic hemospermia is not accompanied by hematuria or by pain It is not associated with pus or with sexual strain Massage of the seminal vesicles will often but not always deliver a bloody fluid. The amount of blood in the semen varies The semen may appear as pure blood There may or may not be infiltrations palpable about the seminal vesicles The condition seems to occur in middle-aged men otherwise in good health The hemospermia may continue for many months or years and shows a great tendency to recur Its sole importance is often related to the apprehension produced by its presence

Prostatorrhea. Prostatorrhea occurs when the muscles of the prostate are relaxed so that movement of the bowels squeezes some drops of opalescent sticky fluid out of the meatus This is harmless

Acute Prostatitis. Acute prostatitis is probably always associated with varying degrees of vesiculitis and urethritis In young and middle-aged men acute prostatitis is often due to gonorrhea, acute infections of the upper part of the respiratory tract, pyelonephritis and urethral stricture and prostatic massage. In old men the causes are pyelonephritis, prostatism, acute respiratory infections and unnecessary prostatic massage.

Urination is frequent, painful and urgent A few drops of urine may pass involuntarily every few minutes

4 to 6 inches (10 to 15 cm.) in diameter The true nature of this midline pelvic tumor is not known until revealed by surgical removal and histologic study.

Concretions and Calculi. A number of concretions or small calculi may be present in the vesicles of the aged

Spermatic colic is rare even in those who have calculi. It may occur at the moment of ejaculation or during sleep. The pain is very sharp and colicky and centralized about an inch up the rectum, or at the neck of the bladder or to the testicle. A painful and deficient emission may ensue. The colic lasts from 10 to 20 minutes and then subsides A hot rectal douche or the introduction of a finger into the rectum with pressure on the offending organ gives relief

Vesiculitis. McCarthy and his associates ventured the opinion that vesiculitis is but a corollary to prostatitis. However, there are three main types of infections of the seminal vesicles. tuberculous, gonorrheal and nonspecific. Congenital anomalies, such as persistence of the müllerian duct or dilatation or stenosis of the ejaculatory ducts, seem to predispose to seminal vesiculitis. Congestion or distention over a long period as the result either of prolonged abstinence or of excessive sexual contact also predisposes to development of vesiculitis in the presence of adjacent or focal infection

The commonest form of seminal vesiculitis is produced by extension of infection *after posterior urethritis This regional extension, which sometimes follows instru*mentation of an infected urethra, occurs either by migration along the contiguous surface of the mucosa or by lymphatic invasion. Infection by means of the blood stream in the course of systemic disease or from foci of infection is possible, as is *secondary involvement from a focus in the epididymis.*

Prostatic disease which interferes with proper drainage of the ejaculatory ducts may set up conditions ideal for the development of vesiculitis Urethral strictures which interfere with the proper drainage of urine from the bladder may result in an infection of the urethra, bladder, prostate and seminal vesicles.

SYMPTOMS Dysuria, frequency and nocturia may be present and may be the only symptoms A morning urethral drop and a light thin watery discharge at the meatus during the day are often caused by a coexistent inflammation of the prostate and posterior urethra Frequent seminal emissions and early ejaculations are common Blood ejaculations are pathognomonic of vesicular involvement. Recurrent epididymitis usually indicates chronic infection of the vesicles

A dull pain or ache in the perineum is evidence of congestion due to prostatovesiculitis. This is characteristic of true visceral pain, which is diffuse, poorly localized and frequently of a dull, boring nature In the more acute processes the severity increases

Pain in the flanks, epigastrium, upper abdominal quadrants, lower abdominal quadrants and suprapubic region may occur as a result of infection in the seminal vesicles, prostate and adjacent structures There may also be present aches and pains of the groins, buttocks, perineum and lower extremities

On digital examination by way of the rectum the swollen and tender vesicle may be felt above and laterally to the prostate

The diagnosis of seminal vesiculitis is made from history, physical examination, microscopic examination of expressed secretions, endoscopy and vesiculography.

Carcinoma. Carcinoma of the seminal vesicles may resemble on palpation metastatic carcinoma situated on the rectal shelf.

The common tumors of the rectal shelf are metastatic lesions, and the greatest incidence of occurrence is found in carcinoma of the stomach It is frequent that patients who have *tumors of the rectal shelf* present a history of gastric complaints, while persons with primary carcinoma of the seminal vesicles frequently present a history of urinary difficulty and hematuria. A point of differentiation between ex-

Abscess of the Prostate. A prostatic abscess results from localization and resolution of prostatic tissue as a consequence of: (1) severe, acute or chronic infections of the prostate, (2) blood-borne infections during the course of severe respiratory infections, furunculosis, carbuncles and osteomyelitis and (3) instrumentation

There is a sudden onset of acute urinary symptoms such as frequent and difficult micturition Perineal pain is commonly present. Fever may reach 103 F or more Leukocytosis of 25,000 cells per cubic millimeter is commonly observed.

On rectal examination the prostate is swollen, tender and contains a fluctuant mass

Tuberculosis of the Prostate. Prostatic tuberculosis is symptomless except for the rigidity which involvement of the gland and of the overlying urethra imparts to the neck of the bladder The resultant achalasia is slight and the symptoms of the tuberculous cystitis are those present in a tuberculous prostate.

On examination there may be large and hard masses of periprostatic exudate These masses may also occur about the subacutely inflamed nontuberculous prostate gland.

The presence of tubercle bacilli in the vesical urine, and the absence of pus and bacilli in the renal urine, as obtained by ureteral catheter, associated with the physical findings of prostatitis or epididymitis, are likely to be symptomatic of tuberculosis. Final diagnosis awaits biopsy if this procedure is deemed prudent.

Tuberculosis of the Epididymis, the Vas and the Testicle. Tuberculosis of the external genitalia of the male may begin by focal infection from the blood stream, or by extension of the disease from the internal genitalia, or by extension to the tunica vaginalis from the hernial sac involved in a tuberculous peritonitis. Suppuration may occur at or below the external inguinal ring but scarcely ever above

The acute onset is characterized by swelling, fever, leukocytosis and pain; the chronic onset, initially by a lump which may be only slightly sensitive. The lesion may remain for years as a nodule of irregular shape without any tendency to suppuration. Such nodules are often felt throughout the epididymis.

the epididymis are important the little round nodules, the diffuse infiltration of the epididymis, the acute epididymo-orchitis; the frequency of hydrocele and abscess; and especially the frequent sensitiveness to pressure and the involvement of the vas.

The discovery of the tubercle bacillus in the urine, in the pus massaged from the prostate, or in the contents of hydrocele fluid or abscess, makes the diagnosis fairly certain

In infancy and childhood the accepted treatment is castration In adult life the tendency toward conservatism is good practice

Prostatic Stones (Concretions). Prostatic concretions occur in men more than 40 years of age. These concretions are small, round, black or brownish bodies impregnated with lime

No symptoms are att

nosed by the shadows

palpated to be thus diagnosed

Prostatism (Stenosis of the Bladder Neck; Hypertrophy of the Prostate). The syndrome of prostatism is produced either by narrowing of the neck of the bladder or by the presence of hypertrophy of the prostate in the neighborhood of the urethra Stenosis of the vesical neck and an enlarged prostate may coexist. However, sclerosis of the vesical neck differs essentially from hypertrophy of the prostate in that it may occur at any age.

The pain is situated on the undersurface of the urethra just behind the glans penis in the perineal region, down the thighs, in the rectum, over the sacrum and often above the pubes.

An acutely inflamed prostate gland may impede the outflow of urine. A fever, the temperature being 101 to 102 F (38.3 to 38 8 C), and leukocytosis are usually present.

The prostate is swollen, tense and tender The examination is performed gently in order to avoid injury and spread of the infection to the periprostatic tissue. If the periprostatic tissue is already inflamed, the outline of the gland is completely lost. The seminal vesicles may be palpable.

The diagnosis is evident from the symptoms and the examination. There may be pre-existing pyelonephritis or such may develop The inflammation in the vesicles often extends to one or both epididymides

Chronic Prostatitis. Chronic prostatitis may follow acute prostatitis, or its onset may be insidious

PATHOLOGY Periacinous infiltration and dilatation of the acini are the essential lesion of chronic prostatitis There usually are regions of normal tissue, and in some instances the diseased tissue is confined to that part of the gland adjacent to the urethra

The normal prostatic fluid is albuminous in appearance and has a characteristic odor It is alkaline to litmus and acid to phenolphthalein It contains gelatinous, transparent lumps of vesicular secretions, translucent lecithin bodies, columnar and round epithelial cells, fewer than 5 leukocytes to the high power microscopic field, a few corpora amylacea, and often spermatozoa Erythrocytes are present in the secretion obtained by massage of the prostate

Purulent prostatic secretion is thin, often yellowish and nonalbuminous in appearance The intensity of the infection is measured by the number of leukocytes and often by the number of bacteria present

SYMPTOMS Generally a chronic prostatitis is symptomless. When symptoms do occur, there is pain, usually in the perineum or occasionally in the lower part of the back The patient may describe it as a discomfort along the urethra, a burning, or a desire to urinate Frequent and difficult urination is due to the chronic posterior urethritis or to sclerosis of the vesical neck.

A disturbance of the sexual function if present is more likely due to age than to the disease Arthritis and other metastatic infections are rarely, if ever, due to inflammation of the prostate

EXAMINATION. The chronically inflamed prostate gland may appear normal on palpation Usually, however, the gland is enlarged The enlargement consists of a general softness of the lateral lobes At times the palpating finger may feel nodules of a somewhat increased resistance in the lateral lobes of the gland. Synchronously with the examination of a swollen prostate, there may be an outpouring of prostatic secretions from the meatus

Prostatic sclerosis is the result of chronic prostatitis of long duration. Scar tissue replaces the parenchymatous exudate, while infection continues in the acini The scar renders the prostate rigid to palpation and invades the neck of the bladder.

Vesiculitis is often a part of the infection which constitutes chronic prostatitis. This may or may not result in palpable enlargement. In longstanding instances the vesicle may be changed to an irregular cavity containing pus

DIAGNOSIS. The diagnosis of chronic prostatitis is made by the discovery of pus and often bacteria in the prostatic secretion Rectal palpation of the chronically inflamed prostate gland may reveal no abnormalities. In some patients the prostate may be tense, firm and bulging, or soft and boggy.

The prostate gland, once severely inflamed, may not become wholly normal. The boggy lobes sometimes but not always can be massaged free of pus, but they remain soft.

or to the symptoms. The symptoms of prostatism are associated with the retention of urine, urinary infection and hemorrhage.

Theories of the etiology of prostatic hypertrophy are enumerated thus: (1) benign ... a product of the disturbed sexual physiology of senility which is ...rnal secretion, (2) arteriosclerosis, (3) adenomatous ... of the breast, (4) myomatous and comparable to ... postgonorrheal, resulting from stricture of the prostatic ducts

PATHOLOGY. There is distention of the glandular acini with proliferation of the epithelium, resulting in the formation of masses of glandular tissue. The glands are surrounded by varying degrees of hypertrophied muscle and hyperplastic fibrous tissue

SYMPTOMS. An important symptom is nocturnal frequency of urination Before there is infection or retention of urine in the bladder, the patient has to arise several times at night to urinate. This nocturia begins by the patient being awakened with ... morn- ... the ... its coming in a small stream, and dribbling at the end of urination. When there is residual urine in the bladder or when the amount of residual urine increases, or infection supervenes, urination becomes painful as well as difficult Voluntary retention of urine or exposure to cold and wet may bring on acute and complete retention of urine as the first symptom Acute complete retention of urine is the first symptom of importance in almost half the cases. Loss of urine may be associated with, may precede or follow acute retention

True incontinence of urine does not occur as the result of prostatism. The loss of urine that does occur is overflow from the atonic, distended bladder The overflow of urine is the result of an irritation of the bladder; the loss of urine is involuntary

Hematuria is common from prostatism, and the presence of blood in urine is not necessarily indicative of the presence of malignant disease. The bleeding is usually due to an ulceration of the middle lobe, to acute inflammation, or perhaps to stone in the bladder Bleeding unavoidably occurs from the passage of instruments

Debility and age are the potent forces which annul the sexual powers Such a loss of function is not due to prostatism The congested prostate may excite abnormal erections which may be interpreted by an atherosclerotic brain as the return of youth and vigor which may lead the patient to the altar of marriage and soon thereafter to disaster

In some aging men an uninfected bladder may reach chronic distention with back pressure extending upward and involving the kidneys before there is known serious trouble. Under such circumstances the first symptom recognized is a loss of weight ... tipation and dry mouth This evidence may be

... r sooner or later in every case and are often initiated by catheterization The cystitis often follows even necessary catheterization The acute cystitis which follows the passage of a catheter begins acutely, often with a chill Spontaneous cystitis is often mild and superficial and may not cause pain or frequency of urination Spontaneous infection rarely, if ever, occurs before the use of the catheter or massage of the prostate for the chronic prostatitis which is present in every instance of infection.

Epididymitis may occur spontaneously or may follow instrumentation Often epididymitis is a symptomless chronic induration at one end of the epididymis Epididymitis may be severe ...

Seminal vesiculitis

The course of the d

vesicoureterorenal reflux of urine. The symptoms of the vesicoureterorenal reflux

Stenosis of the Neck of the Bladder. Stenosis of the vesical neck often is *congenital.* It may become manifest at any age. In infancy the bladder is so vigorous that it dilates with little sacculation in comparison to the megaloureter that ensues. In early life and up to 50 years of age the result of sclerotic obstruction is often diverticularization of the bladder and somewhat less dilatation of the ureter.

Stenosis, whether in the prostate or in the vesical neck, cannot be dismissed with the statement that it is due to inflammation, for gonorrheal urethritis and prostatitis are rarely followed by sclerosis sufficient to obstruct the neck of the bladder. Prostatic abscess rarely results in sclerosis.

Stenosis is commonest between the ages of 30 and 50 years, 20 years or so before the age of maximal incidence of prostatic hypertrophy.

The lesion of the vesical neck comprises chronic inflammation and sclerosis which involve the mucosa, the underlying tissues and the sphincter, often a secondary hypertrophy of the musculature of the bladder follows. The result of such sclerosis is achalasia, rigidity of the vesical neck.

SYMPTOMS. In most instances sclerosis of the neck of the bladder does not cause significant symptoms. Every severe posterior urethritis leaves some scarring about the vesical neck. These scars are not clinically sclerosis until there is retention of urine. The stream loses much of its force; the residuum is constantly at least 50 ml. The urinary stream is slow and small, difficult to start and ends with the dribbling of urine. There is nocturia.

EXAMINATION. Routine examination of the abdomen of a debilitated child may reveal a distended, palpable bladder which indicates the need for a urologic investigation.

Young men affected by stenosis of the neck of the bladder often have been embarrassed when they were boys by being unable to participate in micturition contests and, like girls, by having to urinate in the squatting position.

When the age is attained in which the prostate gland may become hypertrophied, if there is any sclerosis of the vesical neck, symptoms will be more intense and will occur earlier. The symptoms of sclerosis may be overshadowed if there is considerable general hypertrophy. The patient often has achalasia and sclerotic lateral intra-urethral lobes, which give the symptoms common to prostatism.

In *traumatic sclerosis* as the result of external trauma the urethra may be ruptured, for instance, as a complication of a fracture of the pelvis. The more familiar form of traumatic sclerosis, however, is that which follows prostatectomy or resection. After prostatic resection the onset of the lesion cannot be predicted. It may appear, causing retention of urine, before the patient has left the hospital. Symptoms rarely occur, however, before several years have passed.

DIAGNOSIS. The sclerotic bladder, on endoscopic examination, is almost always inflamed and edematous, cystic or ulcerated. Only the well-trained urologist can distinguish the constricting effect of achalasia from the spasm of inflammation and estimate its degree. Also, an expert, and only an expert, by cystometric examination can distinguish the neurogenic atony such as is observed in tabes dorsalis from the muscular atony of the bladder due to sclerosis.

Uncomplicated sclerosis of the neck of the bladder is suspected whenever retention of urine in the bladder is found and rectal touch reveals no enlargement or irregularities in the prostate. A small residuum of urine in the bladder of a patient who has arteriosclerosis and who is neurotic or psychotic does not interfere with the force of the urinary stream.

Hypertrophy of the Prostate. There may be a general hypertrophy of the prostate without significant obstruction to the flow of urine. The syndrome of prostatism depends on either the degree of sclerosis of the neck of the bladder or the presence of hypertrophy of the prostate in the neighborhood of the urethra. The amount of residual urine bears no essential relation to the size of the hypertrophy

partial or complete paralysis of the bladder. The absent ankle jerk is common enough in old age, yet when this sign is noted accompanied with the absence of deep muscle sense, the spinal fluid should be examined.

The prognosis of prostatic retention depends on the patient's age and on the character of the prostatic enlargement.

Tumors of the Prostate Gland. ***Benign Tumors.*** Occasionally *fibromas* and *adenomas* are discovered in the prostate. These usually present the symptoms of benign hypertrophy of the gland

Cysts of the prostate are usually single and apparently due to occlusion of one of the ducts. The cyst may project toward the urethra or the bladder or from the posterior surface or upper border of the gland Intra-urethral cysts grow large enough to cause complete retention of urine Retrovesical prostatic cysts grow to enormous size but do not cause symptoms except from their size.

The intra-urethral cysts usually project characteristically from the upper portion of a lateral lobe. Their translucency may be appreciated on cystoscopic examination

Malignant Tumors. CARCINOMA Cancer of the prostate is present in 1 of every 5 patients who have prostatism Prostatic cancer arises from the epithelium in the terminal acini of the ducts as a single focus or as multiple foci. The disease may remain confined to the gland for a long time Finally, however, the basement membrane is perforated and the neoplastic process passes into the lymphatic structures

The structural type of prostatic carcinoma varies widely. The highly malignant tumors are nearly all highly anaplastic They arise in prostates which have not been the seat of prior disease The tumors are small, regular in outline, and elastic. The lymphatics are invaded uniformly and the small veins are thrombosed early by tumor. There is immediate and widespread metastasis to the bones which may be the first evidence of the disease

The more definite adenocarcinomas are less highly malignant than those characterized by a high degree of anaplasia They invade the stroma more slowly but produce small, very hard, irregular tumors. The lymphatics in the organ are invaded, and metastasis to the regional lymph nodes occurs early in the disease There is a high incidence of perineal, sacral and sciatic pain Some adenocarcinomas may arise in large glands which are often of soft texture Demonstrable metastasis is rare. The true nature of the process is often not discovered until histologic study is made.

Metastasis of carcinoma of the prostate occurs mainly through the lymph vessels. The lymph vessels of the prostate are distributed with the internal iliac vessels and drain to the lumbar lymph nodes, which are continuous with the mediastinal lymph vessels and nodes In the lumbar region the nodes are in close apposition to the vertebrae, so that metastasis to the vertebrae is likely a retrograde extension In the highly malignant tumors the left supraclavicular lymph node is enlarged

Direct extension of the cancerous process into the perineural lymphatics in the prostate gland involves the sciatic plexus and gives rise to sciatic pain Bilateral sciatica in middle-aged men often suggests cancer of the prostate Metastasis less frequently involves the parenchyma of the lungs or liver The process in bone is at first destructive, later there is osteoplasia The deposition of calcium at the periphery of the tumorous deposit gives rise to the roentgenologic findings described as osteoplastic metastasis In some cases the osseous process is wholly destructive and remains so

The initial *symptoms* of cancer of the prostate comprise the urinary symptoms and pain The common urinary symptoms are frequency and difficulty of urination Other symptoms associated with these are nocturia, hematuria, urgency and incontinence Pain accompanying urination, backache, sciatica, or pain in the perineum, rectum or penis may be the cause for the patient to consult a physician

Occasionally, and usually when the tumor is highly malignant, urinary symptoms do not occur, even in well-advanced cancer of the prostate. When present, the

are the same as those of the urethral chill, but of longer duration. The renal infection usually becomes chronic. Pyelonephritis *may not be present, but if present it* may remain slight for years or may soon be complicated by hydronephrosis or may develop into pyonephrosis.

An occasional patient who has prostatism may have a stone in the bladder Stones may be present in those who have but little retention. If removed, stone will recur repeatedly until the prostate is resected.

Examination in Prostatism. A general physical examination is essential for disclosing the effects of prostatism and for determining other disease which is often present. An oval mass above the pubes, palpable bimanually, is a distended bladder. An irregular mass above the pubes may be a carcinoma of the prostate extending around the bladder; an oval mass not palpable bimanually is probably a urachal cyst

The *rectal examination* should not be made until the bladder has been emptied. Observe the patient while he urinates Often there will be this sequence of events: start—stop—start, slow, small stream which ends with weak spurts of urine and finally dies away with dribbles and then drops of urine which trickle over the end of the penis and fall in a backward direction

With the patient leaning forward at a right angle, the examiner's finger is moved across the *prostate gland* The findings of this examination are described with regard to lobal enlargements, smoothness and mobility An enlargement of the lateral lobes is manifested by bulging into the rectum. If the lateral lobes are widely separated, there may be enlargement intravesically, if close together, the enlargement may be intra-urethral. The hypertrophied lobes are usually symmetric, tense and smooth Irregularities felt on or in a lobe may be due to stone, inflammation or carcinoma. The benign prostate is relatively movable, the malignant tends to become fixed, owing to the periprostatic extension of the disease.

The *contraindications to catheterization* are (1) complete retention with distention and (2) acute infection of the prostate and fever Catheterization of a patient who has complete retention with a distended bladder palpable above the pubes is deferred until the patient is in hospital, prepared for decompression.

As the patient urinates, the sluggishness of the stream is noted If there is complete retention, the patient should be sent to hospital for decompression before further examination is made, though if the retention is acute, the bladder may be emptied at once by catheter If the patient has not been catheterized before, a rubber instrument is passed with gentleness, for it is this first catheterization that often infects the patient and may result in serious illness and death. The amount of residual urine is measured.

In the presence of small and even of medium-sized enlargements cystoscopic examination is often necessary in order to search for prostatic bar, diverticulum and tumor

If the patient is to be operated on and is not to be examined cystoscopically, an *excretory pyelogram* is made in order to detect unsuspected urinary stones and functional or anatomic defects in the kidneys. Concentration of urea in the blood is determined and often blood grouping and Rh factors are determined.

Diagnosis of Prostatism. The diagnosis of prostatism is made by the summation of the findings on examination which have been enumerated. Nocturnal polyuria of nephritic or of arteriosclerotic origin is often confusing and is differentiated so that a precise diagnosis of prostatic hypertrophy can be made Renal insufficiency

Tabes dorsalis cannot be distinguished either by the serologic [illegible] absence of knee jerk alone. The Argyll Robertson pupil is often diagnostically helpful. The absence of ankle jerk in association with a loss of deep muscular sense may be the only outward sign of tabes that is early, yet sufficiently ad[illegible] cause

It is realized that regions of increased circumscribed hardness situated within the prostate gland are not pathognomonic of cancer. Such nodules may be due to stone, chronic disease, tuberculosis or chronic prostatitis.

SARCOMA. Sarcoma of the prostate is a highly malignant tumor of connective tissue origin which usually occurs only in infants and children; its rate of growth is extremely rapid, it metastasizes readily to the lungs and is frequently fatal within a few months of its onset. The symptoms which it produces are purely obstructive, complete retention following rapidly the increased difficulty in urination Rectal examination reveals the presence of the large elastic mass which has replaced the prostate Up to date, sarcoma of the prostate has been uniformly fatal and the only available treatment is palliative.

THE PELVIS

The male pelvis is fashioned pre-eminently for locomotion it is both heavier and rougher than the female pelvis The female pelvis, in addition to the functions of locomotion, has the added function of gestation. The cavity of the female pelvis is larger and shallower than that of the male pelvis It is smoother, its bony prominences are less conspicuous. The symphysis pubis is narrower and the sacrum is shorter and less curved The acetabula are set wider apart

Pelvic Hernias. Hernial protrusions of the pelvic contents may occur through the upper portion of the obturator membrane, following the vessels and nerve. Such a protrusion is called an obturator hernia It makes its appearance in Scarpa's triangle and is covered by the pectineus muscle Sciatic hernia is the name given to those forms in which the intestine escapes through the great sciatic notch, passing just above or just below the pyriformis muscle Perineal hernias may push down between the rectum and bladder and bulge in the perineum. They may pass between the coccygeus and levator ani muscles or between the fibers of the latter and bulge into the ischiorectal fossa or forward into the labium of the female

Pain in the External Genitalia. The *labia majora and minora, clitoris, vestibule and urethral meatus* are sensitive to heat, cold and touch. The skin of the labia majora is more sensitive than the skin or the mucous membrane of the labia minora to heat, cold, touch or pinching.

The *urethras* of both men and women before instrumentation are usually sensitive, whereas a much instrumented urethra in either sex may become insensitive Gentleness, persuasion, and reassurance to induce relaxation before and during instrumentation may overcome much of the apparent sensitiveness. The pain elicited by instrumentation of the urethra is due in part to the sudden stretching of a contracted muscle, rather than to the sensitivity of the mucous membrane The passage of the cystoscope may elicit a desire to defecate

Overdistention of the bladder with solutions at any safe temperature produces first a feeling of fullness and then of pain in the suprapubic region and in the urethra, associated with an intense desire to urinate The pain from overdistention of the bladder in men is referred to the end of the penis In women the pain from overdistention is referred to the labia minora and clitoris.

Pain from stimulation of a *ureter* may be felt ipsilaterally, and its location in the skin follows approximately a line drawn along the lateral edge of the rectus muscle. The area of the cutaneous site of pain may be hyperalgesic as tested by pin prick.

When the *ureterovesical junction* and the first 2 inches (5 cm.) of the ureter are distended or stimulated, pain may be felt in the suprapubic region along the urethra and is accompanied by an intense desire to urinate. In some instances the pain extends from the suprapubic region up the midline of the abdomen as far as the umbilicus and may spread across the abdomen In an occasional individual stimulation of the ureter may cause pain along the anterior surface of the thigh and leg to the knee.

Dilatation of the normal *renal pelvis* always elicits pain that is felt in the costovertebral angle There is no recognition of heat or cold sensation in either the renal pelvis

symptoms of urinary difficulties and pain become more severe as the disease progresses.

On *rectal examination* there may be an irregularity of the contour of the prostate or differences in density in various parts of the gland. In advanced prostatic cancer there is an extension of the hard irregular infiltration beyond the confines of the organ, about the base of the bladder and the seminal vesicles, fixing the organ in the pelvis. If there is a large and hard single nodule confined to the organ, it may be due to the presence of stone. Multiple small calculi may produce crepitus when pressure is brought to bear by the examining finger.

Cystoscopic and endoscopic examinations are of little value in early cancer of the prostate The residual urine is measured, and this too is variable. Roentgenologic examination of the bony pelvis and lower lumbar vertebrae will often reveal the presence or absence of metastasis to the bone or the presence of stone in the prostate.

The changes in the values of the acid and alkaline phosphatase in the blood may be of great aid in detecting metastatic lesions in the bone not yet visible by roentgenologic examination

Acid phosphatase is an enzyme which is found in the epithelial cells of the prostate gland in sexually active men and in the cells of prostatic cancer. Values of more than 10 Bodansky units per 100 ml of serum are significant. Normally there is a small amount (less than 3 Bodansky units) of this substance in the blood serum The enzyme owes its existence to the sustaining influence of the male sex hormone After castration it disappears from the prostatic epithelium, and a coincidental shrinkage of the tissues ensues

It is well established that sustained elevation in the serum acid phosphatase level occurs when malignant metastasis has involved the bone marrow and lymph nodes Investigations have shown that transient elevations in the serum titer of this enzyme may be detected after the trauma of operation on the prostate gland and subsequent to digital manipulation, but not as the result of prostatitis, benign prostatic hypertrophy or tumor metastatic to the prostate from other organic structures. Thus sustained abnormal elevations of this enzyme are pathognomonic of metastatic prostatic carcinoma

Alkaline phosphatase is produced by bone as an essential agent for growth and repair The normal values are 1 5 to 4 Bodansky units per 100 ml of serum in adults, and 5 to 14 units per 100 ml of serum in children With few exceptions its serum level reflects bone activity in the absence of hepatic disease. However, in the presence of known metastatic prostatic carcinoma its elevation may signify osteoblastic response to invading tumor and thus serves as an index of the extent of such activity When elevations are present in cancer of the prostate gland, the serum level of the alkaline phosphatase is generally higher than that of the acid phosphatase After castration, when remission occurs, the acid phosphatase level promptly drops to normal, whereas there is a temporary rise in the alkaline phosphatase value, followed later by a drop toward the normal level This behavior affords an index of the effectiveness of treatment

The presence of an abnormal serum acid phosphatase level in the absence of evident metastasis in a patient who has prostatic cancer implies a poor prognosis The presence of a normal serum acid phosphatase value in a patient who has metastatic prostatic carcinoma does not necessarily imply poor response to endocrine therapy. Serum alkaline phosphatase concentration is not in itself specific for prostatic carcinomatous activity without metastasis to the bone.

The *diagnosis* of cancer of the prostate is never certain until biopsy is made at the time of operation. In the presence of urinary difficulties, metastasis to bone and sciatic or perineal pain suggest the diagnosis of cancer of the prostate Add to this a hard, fixed prostate gland on rectal examination and the diagnosis is almost conclusive.

Primary carcinoma of the prostate must be differentiated from secondary carcinoma metastatic from some other primary lesion, particularly rectal carcinoma, and from sarcoma, prostatic cyst, and tumors of the rectum, sigmoid and base of the bladder as well as from the more usual prostatic lesions

broad ligament Cysts arising from Gartner's duct are sometimes found in the vagina. In the male, cysts arising from the wolffian duct are (1) encysted hydrocele of the testicle and (2) general cystic disease of the testicle. Cysts arising from the persistence in the male of Muller's duct have also been observed in the prostate and seminal vesicles, but they are exceedingly rare

This discussion is continued with the description of the disease of each organ.

THE EXTERNAL FEMALE GENITALIA

The labia majora meet anteriorly in the anterior commissure and posteriorly in the posterior commissure They vary greatly in size and in color; often the median sides of the labia are very much more pigmented than the surrounding skin. The space between the posterior commissure and the anus, about 1¼ inches (3.2 cm.), is the perineum.

The labia minora divide anteriorly to form the prepuce above the clitoris and the frenum on its lower surface Posteriorly they decrease in size to a thin crescentic fold of mucous membrane called the fourchet. Like the labia majora, the labia minora vary greatly in size and particularly in the anteroposterior width They often project outside of the labia majora The space between the labia minora is the vestibule. The meatus or urethra is in the vestibule 1 inch (2.5 cm.) behind the clitoris It is surrounded by a ring of mucous membrane, and when a catheter is to be introduced, the urethra can be seen by separating the labia minora, or it can be recognized by the sense of touch The openings of the para-urethral ducts are just below and to the outside of the meatus The vulvovaginal glands (of Bartholin) empty on the inner side of the labia minora in the sulci between them and the hymen.

The hymen partly occludes the lower end of the vagina across its posterior portion The carunculae hymenales are the remains of the ruptured hymen. The fossa navicularis is the space between the hymen and the fourchet.

THE VULVA

The vulva includes the mons veneris, labia majora, labia minora, clitoris and prepuce, vestibule, hymen, urethral meatus and Bartholin's and Skene's glands. Variations in size and true hypertrophies of the clitoris and labia minora are common In rare instances there may be a complete double vulva

The vulva becomes edematous when there is edema of the extremities as in congestive heart failure. Varicosities of the vulva may be associated with varicose veins of the legs Hematomas occur in the normal vulva after trauma. They may become large and painful

Acute Vulvitis. Acute nonvenereal vulvitis includes intertrigo, a diffuse reddening of the skin of the vulva and folds of the thigh, which occurs in infants and obese women, mainly during hot weather Follicular vulvitis or hair follicle infection is common Furunculosis or boils may develop in hair follicles Noma, a gangrenous vulvitis in young girls in tropical climates, follows severe systemic infections such [illegible] The diabetic [illegible] itis

[illegible] Bartholin's and Skene's glands, is not ordinarily involved in gonococcal infections, and the majority of th[illegible]

[illegible] is occasionally seen [illegible] is common in children The vagina is inflamed and there may be redness and swelling of the vulva.

Weaver stresses the value of bacteriologic cultures in the detection of the gonococcus in contrast to the inadequacy of the stained smear, pointing out that in known

or the ureters. Lennander observed that the outer surface of the kidney could be pinched, cut, or have heat and cold applied without eliciting any sensation.

Distention of the right renal pelvis may produce pain *extending down toward the* right groin, and sometimes spreading to the urethra and testicle Ockerblad and Carlson observed that faradic stimulation *within the renal pelvis* always elicited pain which was felt on the back at the costovertebral angle and that the pain never extended around to the front, nor upward from this point.

THE FEMALE GENITALIA

Aberrations of the Female Genitalia and Their Correlations with Homologous Structures in the Male. The wolffian duct with a collection of tubules is known as the wolffian body, and reaches its full development in the seventh week. On one side of the wolffian body develops the sexual gland, which later becomes in the male a testicle, in the female an ovary By the end of the second month the kidney develops at the caudate extremity of the wolffian body. At this time the bladder is connected by the urachus with the stalk of the allantois The lower end of the bladder is connected with the extremity of the intestinal tract through a dilatation called the urogenital sinus The union of the *urogenital sinus and intestine forms the cloaca At the time the* wolffian body is developing, there appears alongside of it a tube called Muller's duct This duct atrophies in the male but in the female becomes the uterine tube, uterus and vagina. The ureter is developed and becomes connected with the lower portion of the bladder.

The wolffian duct and the mullerian duct, until about the third month, empty into the urogenital sinus. Differentiation of the sexes begins about the third month and is well advanced in the fifth. As stated, the sexual gland in the male becomes the testicle, and passing from its lower end is seen the gubernaculum In the female the sexual gland becomes the ovary, and the round ligament passes from its lower end The wolffian body, after performing temporarily the functions of a kidney, disappears, leaving sometimes a small cyst, known as the hydatid of Morgagni (stalked hydatid), attached to the upper part of the epididymis in the male and in the broad ligament near the ovary in the female In the lower portion of the hydatid are the remains of the wolffian body comprising some short closed tubes in the tail of the epididymis known as the paradidymis or organ of Giraldès in the male, and the paroophoron of the broad ligament *in the female The wolffian duct, which forms the vas deferens and part of the* epididymis in the male, forms the atrophied paroophoron in the female to the inner side of the ovary.

The parovarium or organ of Rosenmuller is the remains of the middle set of wolffian tubules and in the male forms the epididymis In the female it is almost always present as a horizontal tube with shorter tubes connected with it, between the layers of the broad ligament near the ovary The wolffian duct may persist as a small tube, known as the duct of Gartner, in the broad ligament close to the uterus and vagina In the male the mullerian ducts atrophy and form the sinus pocularis of the prostate Part of them may persist patulous as Rathke's duct As stated, in the female they form the uterine tubes, uterus and vagina

Exstrophy of the bladder, epispadias, hypospadias and *various forms of* hermaphroditism result when the walls of the bladder and urethra and external genitals fail to develop in the median line Should the urachus not close, a fistulous tract leads from the bladder to the umbilicus from which urine discharges Cysts may also form in its course If the partition between the rectum and the anus is not absorbed, there is formed *one of the varieties of imperforate anus. In some cases* the rectum empties into the urethra or bladder, thus forming a cloaca Should the testicle become arrested in its descent from the region of the kidney, it forms what is known as undescended testicle It may be arrested within the abdominal cavity, in the inguinal canal, or near the external abdominal ring.

The paroophoron *gives rise to cysts which have a tendency* to develop between the layers of the broad ligament and are papillomatous inside. The parovarium also gives rise to cysts which likewise tend to burrow between the layers of the

The lesion may occur on other portions of the skin such as the face, neck, and back. Often the gross appearance is most characteristic.

The diagnosis is based on the results of examination of scrapings from the ulcer stained with Wright's stain or Giemsa's stain; the presence of Donovan bodies (Donovania granulomatis) as clusters of cocci, some occurring particularly in large endothelial cells, but also in monocytes, leukocytes, and in clusters outside of cells partially contained in a membrane, has been accepted as diagnostic Some of the organisms are surrounded by thick, dark capsules All other venereal diseases must be ruled out by serologic examinations and skin tests.

Lymphopathia Venereum and Psittacosis Viruses. Synonyms for lymphopathia venereum are climatic bubo, tropical bubo, venereal bubo, fourth venereal disease, sixth venereal disease, lymphogranuloma inguinale, granulomatous lymphomatosis, poradenitis, esthiomene, and maladie de Nicolas et Favre.

Lymphopathia venereum is a protean disease usually transmitted by venereal contact, and manifested by both constitutional symptoms and acute and chronic tissue changes in the inguinal and anorectal regions. It is caused by a virus which is similar to that which produces psittacosis.

In the first stage it forms a superficial ulcer which varies from a few millimeters to ⅘ inch (2 cm) in diameter This primary lesion may occur at any point in the vestibule or inner surfaces of the labia, commonly on the urethra or in the fourchet. It may disappear soon or may develop into a deep lesion on the vulva or on the sides of the vaginal orifice, completely destroying the urethra. If the primary lesion occurs on the upper two thirds of the vulva, the lymphatics drain to the inguinal lymph nodes, with formation of bubo and perhaps multiple draining sinuses Not infrequently the lymphatic channels of the vulva are blocked, forming elephantiasis, chronic hypertrophic vulvitis or esthiomene Inguinal involvement in women is less common and less severe than in men If the virus involves the urethra, ulceration and strictures may follow Because of the lymphatic drainage from the primary lesion, rectal strictures are commoner in women than in men. Diagnosis of the late lesions may be fairly accurate from the gross appearance, but should be substantiated by exclusion of other lesions.

Lymphopathia venereum must be differentiated from chancroid, bubo due to pyogenic lesions of the lower extremities, tuberculosis of the inguinal lymph nodes, gonorrhea, syphilis, granuloma inguinale, balanitis, plague, tularemia, carcinoma and tuberculosis of the rectum, and ulcerative colitis Films of pus or biopsy material are examined for elementary bodies by means of the Macchiavello stain *Suspected material should be inoculated intracerebrally into mice.* The serologic tests for syphilis, Ducrey's skin test, darkfield, smears, scrapings, and biopsy and the Frei test all are performed as parts of the differential diagnosis.

The Frei test consists of the intradermal injection of 0.1 ml of antigen and 0 1 ml. of control material Results of the test are read 48 to 96 hours after injection, and, if the reaction is positive, the central induration of the papule caused by the antigen measures 6 by 6 mm or more, while that caused by the control material measures 5 by 5 mm or less

Reaction to the Frei test usually becomes positive 7 to 40 days after the onset of the adenitis Negative reactions in definite cases are rare, they are usually due to such factors as the menses, septicemia, fever, tuberculosis, and coexistent early syphilis or early chancroid

Axelrod tested the yolk sac virus antigen of venereal lymphogranuloma and found that the results of the virus antigen are consistent with positive history and signs of the disease. This test has not come into wide clinical use Bedson and co-workers demonstrated that titers of 1 32 or more in the complement fixation test made with steamed virus of lymphogranuloma venereum and the serum samples from patients in whom the clinical observations are compatible with a diagnosis of lymphogranuloma venereum

cases of gonorrhea in women gram-negative diplococci may be found in stained smears in less than 20 per cent of the cases, whereas cultures on proteose peptone hemoglobin agar yield a correct diagnosis in more than 75 per cent. At Weaver's laboratory, when oxidase-positve gram-negative diplococci are found on cultures, they are further studied from the standpoint of their fermentation reactions on various sugars The gonococci will ferment glucose but none of the other sugars *Neisseria sicca* ferments all the sugars except mannitol It is this organism to which Weaver calls special attention, because physicians who depend on staining procedures for the diagnosis may make false positive diagnoses

Syphilis. A chancre is often situated near the vaginal orifice on a labium majus or minus or about the rectum. It is a grayish, granular ulcer, round or oval, from ⅖ to ⅘ inch (1 to 2 cm) in diameter, raised, flat and firm Multiple chancres occur in the folds where the labia are in contact. The diagnosis is proved by darkfield examination, demonstrating the spirochetes.

Secondary lesions occur as condylomata lata and mucous patches. The tertiary lesion forms deep crater-like ulcerations Diagnosis is suggested by results of the histologic examination and disappearance of the lesion under antisyphilitic therapy. Positive results of serologic tests are present when the lesions are secondary and tertiary, but by no means are these diagnostic of vulval syphilis. Tertiary syphilitic manifestations originate extremely infrequently in the vagina. The isolated submucous gumma breaks down early and appears in the form of a characteristic ulcer.

Granuloma Inguinale. There are three infections of the anorectal regions and external genitalia of both men and women which are characterized by ulcerations and inguinal lymph-node involvement, ulceration of the skin or mucous membranes, and often abscess formation These are (1) granuloma inguinale, (2) lymphopathia venereum and (3) soft chancre (see also page 410)

Granuloma inguinale is a bacterial disease, the exact causative bacterium is unknown Lymphopathia venereum is a viral disease, and soft chancre is caused by *Hemophilus ducreyi*

Granuloma inguinale originates from the organisms which produce Donovania granulomatis The disease is largely limited to Negroes or to persons of mixed race who have Negro blood Granuloma inguinale or granuloma venereum or pudendal ulcer is primarily a disease of the skin, producing an ulceration which has a tendency to extend from the vulva to the inguinal regions.

Packer, Turner and Dulaney called attention to the fact that the earlier concepts of the progress of this infection solely by serpiginous spread or by auto-inoculation have been broadened in recent years as a result of accumulated evidence of lymphatic spread and involvement To lymphatic spread has also been attributed the extensive involvement of the pelvic organs following granuloma inguinale of the cervix and vagina Of significance are the pronounced systemic manifestations which are frequently associated with lesions in this region, particularly when complicated by pregnancy These systemic manifestations indicate that granuloma inguinale, far from being strictly a local disease of the genitalia, has potentialities for widespread dissemination throughout the body, either of the specific etiologic agent or of the products of secondary invaders The former possibility has already been demonstrated by a few reported cases of metastatic lesions of bones and joints in distant parts of the body following lesions of the genitalia Thus has evolved from the early beliefs of the limited implications of this disease a clearer understanding of the possibilities for widespread dissemination which the disease possesses

The initial lesion begins as a papule ⅕ to 1⅔ inches (1 to 4 2 cm.) in diameter, develops into an ulcer, and may denude the skin of the vulva, perineum and gluteal folds. The cutaneous margin of the ulcer is raised and pigmented and has a serpiginous border and a bright pinkish red granular-appearing base which reflects light

glands. These lesions may itch. Urine may be a constant cause of irritation and burning

Collections of smegma round the clitoris or in the folds between the labia are prone to produce irritation and mild itching sensations. A persistent and irritated hymen, everted vaginal mucosa due to relaxed vaginal outlet, gonorrheal warts, leukoplakia, vulvitis, and ulcerative or neoplastic diseases of the vagina or external genitalia all may cause itching.

Protective pads or intravaginal tampons used to absorb menstrual and leukorrheal secretions may be responsible for irritations and itching. Dermatologic factors include infections of the hair follicles and sweat glands, fissures in the skin, dry scaly dermatitis in which the skin becomes diffusely irritated, reddened, purplish or grayish and appearing as if it had been scalded. A rare form of pruritus is itching which involves the fossa navicularis, vestibule or interior of the vagina

Vaginismus. This is a painful spasm of the vagina due to local hyperesthesia. Vaginismus is termed superficial when the discomfort is at the entrance of the vagina. It is termed deep when the discomfort is situated deep and seemingly in the bulbocavernosus or in the levator ani muscles. In some instances the discomfort is apparently due to spasm of the constrictor vaginae muscle Vaginismus is termed psychic when there is extreme aversion to coitus The act is attended apparently by painful contraction of all of the muscles of the vagina

Nymphomania. The term nymphomania is employed to designate an exaggerated sexual desire in a woman It is a condition the opposite of vaginismus and, like the psychic form of vaginismus, it has nothing to do with the state of physical health or the hormones of the glands of internal secretion These women often have had abnormal sexual experiences and frustrations This condition is often present as a part of schizophrenic psychosis

On examination the labia are large and have a rugged appearance and may be excessively pigmented

Leukoplakia Vulvae. The term leukoplakia vulvae refers to areas of thickening on the skin The cause of leukoplakia is unknown The disease is characterized by translucent white patches of irregular size which may have indefinite borders or may be widespread It occurs particularly about the clitoris, labia minora, and on the perineum It may occur inside the rectum Very commonly there is associated kraurosis Pruritus is common and severe Lichen planus and leukoplakia bear a great resemblance to each other when situated on the vulva In lichen planus similar lesions will be present on the flexor aspects of the forearms, fronts of the legs and perhaps in the mouth

In the differential diagnosis lichen planus is to be excluded Lichenification is differentiated by the fact that it commonly follows protracted pruritus. The spots of lichenification are thickened, diffuse, usually symmetric, situated more on the outer parts of the labia majora and between the buttocks round the anus than elsewhere. Lichenification is usually moist and has fissures

Leukoplakia represents a truly premalignant lesion

Tumors of the Vulva. *Benign Tumors.* *Condyloma acuminatum* (verruca acuminata), or venereal wart, is often the result of unsanitary conditions Warts of this type are common in the obese, during pregnancy, and in association with gonorrhea

Verrucae acuminatae occur on the vulva, in the vagina and urethra and on the cervix. They may be a few millimeters in diameter or a cauliflower mass that almost covers the external genitals They are distinguished from the flat, sessile condylomata lata

Fibromas and *fibrolipomas* of the vulva are common. The fibroma is hard and movable and is covered by healthy skin. It is usually small. The fibrolipoma is

suggest active infection with the virus of lymphogranuloma venereum. The serums from human infections with the viruses of psittacosis and lymphogranuloma venereum show a high degree of cross reaction in the complement fixation test with antigens made from these two viruses. The Frei test also merely indicates that infection with a virus of the lymphogranuloma venereum and psittacosis group has occurred A positive reaction to a Frei test together with a positive reaction to a complement fixation test at a serum dilution of 1 . 16 or more in a patient suspected of having lymphogranuloma venereum is good evidence of active infection with the disease Acid extracts of lymphogranuloma venereum and psittacosis viruses appear to give specific reactions when injected intradermally in human infections with these two viruses

Herpes. Herpes genitalis in women is due to the herpes simplex group of viruses which affect the mouth and nose, and the male genitalia Bullous lesions may occur singly or multiply or extensively. Ordinarily, however, a single vesicle, followed by an ulcer, appears about the labium or the vaginal orifice.

The blisters may break and form numerous small superficial tender ulcers. At times it has been thought that herpes is transmitted by sexual intercourse, but it often occurs without intercourse Occasionally the ulcers recur with each menstrual period In such cases the diagnosis is not difficult. Smallpox vaccine has been used for treatment with some success

Ecthyma of the Vulva. Ecthyma of the vulva resembles condyloma latum. The lesions begin as pustules and form depressed ulcerations. *Staphylococcus aureus* and *Streptococcus pyogenes* may be cultured.

Kraurosis Vulvae. In kraurosis vulvae the skin is white, red or mottled and appears dry and thin There is a progressive shrinkage of the vaginal orifice, labia minora and clitoris, and of the labia majora. The mucosal border seems to extend beyond the normal confines and has a smooth glistening unhealthy appearance Kraurosis is common after the menopause Pruritus may be associated, with secondary infection incident to injury of the skin from scratching. Inflammatory ulcerations are slow in healing, mainly because of persistent irritation

Disease of the Vulva Due to Disturbances of Innervation or to Absence of Psychic Control. ***Pruritus Vulvae.*** Intense itching is a symptom of various skin diseases and may occur idiopathically as a neurosis. Itching may be an undesirable normal impulse, for it is present in varying degrees each day in every man, woman and child. If judgment can be rendered from observations of them scratching or making various rubbing movements as substitutes for scratching, all mammals are likewise troubled almost constantly by itching about the anus and genitalia

In women genital and perineal pruritus is common and is perhaps the most disabling form of pruritus It may be temporary and insignificant, such as the itching that is often felt during menstruation; on the other hand, it may become a fixed obsession. The irrepressible impulse to scratch creates a vicious cycle, for scratching makes itching As an obsession a pruritus gives its victim very little rest or peace, and eventually there is present a deterioration of the disposition and health

Senile and atrophic changes in the skin, due to a normal or artificial menopause or irradiation therapy, are frequently accompanied by pruritus. In these conditions the skin becomes thin and wrinkled, loses its resistance to infection, and becomes susceptible to irritation.

Pruritus ani and vulvae are common in obese women whose genitals are constantly wet with perspiration.

Rectal discharges and intestinal infections may cause pruritus Also disorders such as hemorrhoids, proctitis, parasitic intestinal infections, fissure and rectal polyps are frequently the basis of the trouble. Pruritus may be ascribed to diabetes mellitus. However, in practice the impression is gained that most instances of pruritus are not associated with diabetes.

In some cases pruritus starts as urethritis or as an infection of the periurethral

Urethritis. Urethritis is an inflammation of the mucous membrane of the urethra. It may be either acute or chronic.

ACUTE URETHRITIS. The female urethra is short and straight and has a wide caliber, and urethritis is therefore almost always a temporary condition. However, if the periurethral glands are involved, they may affect the urethra and bladder permanently Stricture of the urethra is not common in women

The chief symptom of urethritis is burning on urination. If there is frequency, one suspects some disorder (cystitis) within the urine-containing viscera There may be a constant burning or itching sensation.

On examination, in the acute stage, the urethral meatus is swollen and red, and pus can be expressed from its lumen. The infection usually involves also the submucous tissues and the periurethral ducts of Skene and any glands or congenital diverticula that may be situated along the urethral canal.

CHRONIC URETHRITIS Chronic urethritis in the female has no distinguishing features except for the exacerbations of the acute urethritis it originates.

On examination the urethra may feel thick and it is sensitive. The diagnosis is made by endoscopic examination In addition to the evidence for a chronic inflammation there are cystic changes in the urethral epithelium

Relaxation of the Vesical Sphincter. The vesical sphincter normally is sufficiently strong to hold urine under excitement, coughing, sneezing or lifting. It is a common experience in parous women that coughing will be accompanied by a loss of a few drops of urine. In man and other mammals excessive fear, fright or pain will be accompanied by a loss of urine This is called stress incontinence and is a normal act.

Stress incontinence of a marked degree may occur in virgins, neurotic men and nulliparous women In such instances it is due to an overreaction to which these individuals are subject. There is no organic disease of the urinary structures.

Childbirth Injuries of the Urethra. Childbirth injuries comprise urethrocele, relaxation of the vesical sphincter, and urethral fistulas

Urethrocele usually accompanies *cystocele*. It is a relaxation of the anterior vaginal wall in the region of the urethra. The symptoms are identical in both cases. Not infrequently a urethrocele remains after the cystocele has been repaired surgically unless the urethrocele is discovered and corrected at the same time. This may account for the persistence of symptoms after a cystocele has been surgically repaired

Urethral Obstruction. Urethral obstruction in women is uncommon It is unusual for a woman to have stricture of the urethra subsequent to gonorrhea or other infections

A urethral obstruction may be partial or complete, acute, or chronically slow in development depending on its cause

Partial obstruction occurs in middle-aged women as a sequel of chronic infections resulting from trauma of coitus, childbirth or, in elderly women, from senile changes in the mucous membrane. Unusual causes are extensive inflammatory lesions and tumors In middle-aged women the obstruction usually is situated in the outer third of the urethra or at the external orifice. The orifice is so small that a ureteral catheter is passed with difficulty

The symptoms of partial obstruction are difficult and slow urination, burning, frequency, urgency and pain There is often an associated recurring cystitis As soon as the urethra is completely cured, the cystitis usually disappears.

In the aged woman who has a small urethral orifice, normal functioning may be carried on for a long time The onset of any superimposed inflammatory reaction, however, soon causes enough edema to transform such a lesion into a complete obstruction

On examination the urethra is more rigid than normal and it feels indurated

usually softer, may be attached to the skin by fibrous bands, and is often lobulated Occasionally a fibrolipoma becomes pedunculated, and may attain large size.

Sebaceous cysts are common in the vulvar skin. Usually they are round or oval and project above the skin. Their characteristic appearance is a grayish color, the overlying skin being tense, adherent and thin. The whole tumor is freely movable

Sweat gland tumors (hidradenoma) are uncommon growths that originate in the sweat glands of the labia The tumors ordinarily are not more than ⅖ or ⅘ inch (1 or 2 cm) in diameter. They occur in older, or at least middle-aged, women The lesions are smooth and covered by normal skin, resembling small subcutaneous fibrolipomas or sebaceous cysts Openings in the overlying skin may suggest that the lesion is a sebaceous cyst. The histologic appearance may suggest adenocarcinoma

Malignant Tumors. *Carcinoma of the vulva* is primarily a disease of women past the menopause, although it occurs at times in younger women The average age of the patients is about 60 years These carcinomas are of the squamous cell variety arising from the skin at mucocutaneous borders. The lesions appear on the labia, on the clitoris or in the vestibule They often are associated with leukoplakia or with carcinoma of the rectum. They do not develop rapidly but ulcerate early The lesion becomes a nodular, weeping, putrid-smelling ulcerated mass It is diagnosed by biopsy and histologic examination

Adenocarcinomas of Bartholin's glands are rare. They appear as hard nodules beneath the skin in the region of the gland. Occasionally adenocarcinomas arise from the sweat glands. Secondary adenocarcinomas arising from the uterus or rectum form hard undermining ulcerations in the vulva Diagnosis is by histologic study of biopsied tissues.

Melanotic sarcoma and *sarcoma* on the vulva are rare

THE FEMALE URETHRA

The female urethra, 1⅗ to 2⅖ inches (4 to 6 cm.) long, leads from the vestibule to the bladder The external urethral orifice is usually situated about halfway between the clitoris and the anterior margin of the vaginal orifice

It is subjected to and may be injured by the discharges from the uterus and vagina, and may be contaminated by feces, especially in infants and in adults who have incompetent anal sphincters The urethra is easily traumatized in childbirth

Skene's ducts or glands open into the urethra immediately within the external meatus Other than Skene's glands, Cabot and Shoemaker observed only epithelial crypts and recesses which perhaps were the rudiments of embryonic glandular structures but not true urethral glands. Urethral diverticula are rare

Hypospadias. *The female urethral orifice normally is situated* well above the vaginal margin and is clearly visible However, it may occupy a lower position and open into the vagina This abnormality is due to arrested development of the urogenital sinus and to incomplete separation of the orifices of the urethra and vagina.

The extreme malformation is observed when the vagina opens into the *posterior* urethra This is seen only in the presence of gross malformation such as hermaphroditism.

Hypospadias *in* women rarely causes any notable symptoms Occasionally it may produce external irritation, especially on intercourse In some instances this condition favors the development and persistence of urethritis and cystitis

Infections of the Urethra. The urethra is often a portal of infection in girls during childhood. Skene's ducts *externally and some glands and epithelial* crypts in the posterior portion of the urethra may maintain infections and cause recurrences of cystitis. In women gonococcal infection in diverticula or in Skene's glands may be the focus of reinfection Glands along the posterior part of the urethra and even diverticula are difficult to discover on endoscopic examination

Urethrocele is a herniation through the urethrovaginal septum and not through the urethral meatus

THE INTERNAL FEMALE GENITAL ORGANS

EXAMINATION. The examination of the female genital organs is performed with the patient in any one of four positions It is assumed that the patient is fully undressed and that all unnecessary exposure is avoided

1 The routine examination is conducted with the patient lying on her back, on an appropriate examining table, with her knees flexed, and hips fully flexed, the thighs drawn up on the abdomen, and the coccyx lifted so as to lessen the inclination of the pelvis. The heels support the flexed legs on stirrups on the corners of the table, or the thighs are supported by leg holders or are held by assistants

2. A position especially valuable for examination of the portio vaginalis, the rectum and the bladder is the knee-chest position. The elbows and knees of the patient support the body The shoulder girdle is in a low position, while the back and buttocks are high. The abdominal and pelvis viscera fall toward the diaphragm, and the attachments of the pelvic organs are stretched.

3. To afford a better view of the cervix the patient lies on her left side with the left arm behind her and allows the right shoulder to sink as far forward or downward as possible, the abdomen and thorax resting on the table. The knees are flexed, and the thighs drawn up (Sims' position).

4 The standing posture is especially valuable if the patient has a descensus or other displacement of the pelvic organs For this examination have the patient stand with one foot on a low stool before the examiner In this posture the degree of descensus can be determined and the posterior and lateral walls of the pelvis can be thoroughly palpated.

It may occasionally be necessary to anesthetize the patient in order to relax the parts for examination, but the greater the experience of the physician, the less often will this method be required In young unmarried women a rectal examination will usually suffice

A pelvic examination is never performed without knowing that the bladder is empty For the examination of the female pelvis the index and middle fingers are used The hand may be covered with a rubber glove or the fingers covered with finger cots. The covered fingers are lubricated The fingers are introduced into the vagina if the outlet is marital If the outlet is virginal, only a rectal examination is made

Bimanual Examination After the preliminary examination of the vagina and cervix, the exact position of the *portio vaginalis* or *cervix* is ascertained Normally, when the uterus is in the position of anteversion, it lies behind the spinal line (connecting the spines of the ischia), the external orifice of the uterus, or os, being directed backward, and the anterior lip being longer than the posterior. The cervix should lie approximately in the median line.

Bimanually to palpate an anteverted *uterus*, the examiner places the fingers of one hand above the right pubic bone and presses gradually into the depth, while the fingers in the vagina, one finger on the anterior lip of the cervix, shove the tissues just in front of the cervix strongly upward. As soon as a resistance is felt by the external hand, the pressure of both hands may be slightly increased, when the body of the uterus can be felt between the two hands. Or, the fingers in the vagina may press forward from the posterior wall, in which event the portio vaginalis, along with the body of the uterus, is shoved against the external hand. Should the uterus lie abnormally high, it may be necessary to press with the fingers directly against the tip of the cervix in order satisfactorily to palpate the uterine body.

To make sure whether a resistance felt is really due to the body of the uterus, a test is made to ascertain whether the portio vaginalis, which is certainly a part of

Obstruction by extrinsic tumors is obvious. On direct endoscopic examination by one trained sufficiently to perform such an examination, the urethra is red and inflamed, the normal longitudinal striae are absent and the mucous membrane is injected. There may be hypertrophy of the bladder, as evidenced by a mucous membrane which is irregular, owing to trabeculations of the hypertrophied muscle and inflammation If overdistention and dilatation persist, hydronephrosis and impairment of renal functional activity ensues.

The diagnosis is made by inspection and palpation of the urethra and the passage of urethral sounds and dilators by skilled hands.

Incontinence. On occasion, in men, women and children, the bladder gradually becomes distended with urine because of some neurogenic or organic disturbance in the passage of urine so that it is never completely emptied When the bladder becomes distended to its full capacity and empties only by the pressure of the abdominal wall, the condition is called paradoxical incontinence. The overflow voiding may be practiced by the patient who learns that voiding may be accomplished by flexion or bending the body forward often while at stool. The amount of urine is normal, and frequency of urination occurs without intervening incontinence In these patients the full bladder on palpation simulates an abdominal tumor.

Enlargements and Tumors of the Urethral Meatus and Urethra. *Eversion* of the urethral mucosa is common in women because the boundary separating the mucosa of the urethral canal and the surrounding epithelium of the vestibule is not constant, and often this inconstancy is increased by a widely patulous meatus. This eversion and redundancy of the urethral mucosa is symptomless and does not require treatment

Prolapse of the urethral mucosa may occur. In this condition the urethral mucosa everts itself and projects from the urethral orifice The protruding mass is extremely sensitive and bleeds easily It may be difficult to tell whether the mass is a prolapsed urethral tumor or prolapsed and congested urethral mucosa

Urethrocele or prolapse of the mucous membrane of the urethra has been observed in girls less than 15 years of age. The cause is unknown

Primary tumors of the urethra are rare, but secondary tumors are common. Carcinomas of the bladder, rectum, cervix and anterior vaginal wall may extend to involve the urethra

Benign tumors of the urethra are *urethral caruncles,* in reality polyps of the urethral mucosa. Caruncles are small and are situated near the external meatus They may occur singly or multiply Urethral caruncles are occasionally malignant and therefore biopsy should be performed and they should be treated surgically. Caruncles are symptomless until the mass becomes large The symptoms, when the caruncle is large, are bleeding, pain and dysuria On examination there is a dark red mass protruding from or lying in the urethral meatus Biopsy is diagnostic.

Urethral polyps are not common and are situated in the middle or the posterior portion of the urethra They have the same features as urethral caruncles The diagnosis is made by the endoscopic examination, and when found, the polyps are removed

Malignant tumors of the urethra, *primary carcinomas* and *sarcomas,* like benign urethral tumors, are rare They are distinguished from benign caruncles, polyps, eversion and other lesions by biopsy and microscopic examination

When a mass is found anterior to the vaginal orifice, the correct relationship of the urethral canal to the *mass is ascertained. In a true prolapse the lumen* is directly in the center of the mass Occasionally this condition must be differentiated from urethral polyp, caruncle, condyloma, urethrocele and carcinoma. In urethral polyps the polyp is in the center of the lumen, and the mucosa is around it In caruncle the lesion is usually found only on the posterior lip of the meatus and is very sensitive to touch Condyloma has a warty, fungoid appearance and is usually multiple

The ovaries are frequently found in an unusual position The ovary is recognized by (1) its position, (2) its flattened ellipsoid shape, (3) its movability, (4) its elasticity and (5) its normal characteristic tenderness

In many adults prolapse of the ovary is found, the organ on one or on each side is down in the recto-uterine pouch where it may be either loose or fixed. Often it is very tender.

The vagina and cervix are examined by means of the vaginal speculum. For most purposes, the bivalve speculum is perfectly satisfactory. It is made in several sizes, and the examiner selects that size which can be introduced easily. In children, the most satisfactory speculum is a small cystoscope, which is used in the knee-chest position. In adults, if the hymen is unruptured, one may use a very small bivalve speculum

To introduce the bivalve speculum, one turns it so that its long axis is vertical, to conform to the shape of the vaginal orifice. A lubricant facilitates the introduction of the speculum The common practice of using green soap as a lubricant is not advisable on the first examination, because soap alters the chemical reaction of the vaginal secretions and interferes with staining and cultural reactions. Hence, water or a drop of some jelly on the outer surface of the speculum is a better lubricant

THE VAGINA

The vagina is about 3 inches (7 6 cm) long; its posterior wall is longer than the anterior, being 3½ inches (8 9 cm) long The hollow formed by the anterior wall of the vagina blending with the anterior lip of the cervix is the anterior fornix The depression behind the posterior lip is the posterior fornix, behind which is Douglas' pouch At the vulvar outlet the lumen of the vagina is anteroposterior in direction, it then changes to lateral and at the cervix becomes round Its walls are in contact

Congenital Malformations. Absence of vagina, absence of uterus, double uterus, septate uterus, bicornate uterus, double cervix, and double or septate vagina are anomalies due to *inhibition in the development of the mullerian ducts* The ducts are differentiated and attain a certain degree of development, then, for some reason, normal progress is arrested The result is any one of the aforesaid uterine and vaginal malformations, depending on the point at which fusion is stopped and the amount of maturity which each mullerian duct acquires independently

When there is *nonunion* of the mullerian ducts, the uterus and upper part of the vagina are absent The uterine tubes are separately situated in the lateral parts of the pelvis and each terminates separately and blindly near the midline behind the bladder. These mesial ends often form bulbous enlargements 1 cm. in diameter which are attached to the round ligaments The defect is usually limited to the mullerian ducts, so that ovaries, external genitalia, hymen, vaginal orifice and external segment of the vagina are normal

Women who lack the uterus and vagina menstruate into a uterine tube As the result of successive menstruation into the tubes large pelvic masses are formed

Incomplete union of the mullerian ducts permits of a great variety of uterine and

uterus, and varying grades of duplication may be present One half of the uterus may be normal, the other being a rudimentary horn There may be only one cervix; there may be two. Such defects usually cause no symptoms at all, at times, pregnancy may develop in a rudimentary horn and may lead to serious consequences

The *vaginal defects* due to incomplete union of the mullerian ducts may result in a vertical septum which completely divides the vagina (septate vagina). These septa do not cause serious inconvenience.

Congenital absence or atresia of the vagina may involve the external or the internal part of the vagina.

the uterus, is connected or not connected with the resistance. In addition, dependence is placed on the form and consistency of the uterus as felt by the external hand. The mobility of the uterus (body and cervix) varies according to size and weight of the uterus, the condition of its ligaments, the tension of the abdominal walls, and the state of the adjacent organs. Normally it should be easily possible to press the uterus, with its fundus, upward as far as the upper margin of the symphysis pubis.

The angle between the cervix and the body, when the urinary bladder is empty, is obtuse in normal anteversion and acute in anteflexion. The normal uterus is in a position of antedextroversion, the middle of the fundus gravitating slightly to the right.

On pressing firmly with the two hands near the lateral margins of the uterus, the *broad ligament* (ligamentum latum uteri) on each side may be examined, and abnormal conditions of the parametrium will be found, if present, in the transverse pelvic diameter, to the right and to the left of the uterus.

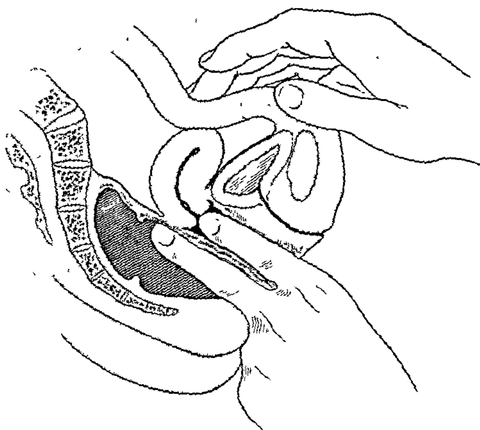

Fig 7-4 Pelvic examination with simultaneous examinations from the rectum and vagina

The *pouch of Douglas* (recto-uterine pouch) behind the uterus and the *peritoneal pocket* between the uterus and the bladder (vesico-uterine pouch) cannot be demonstrated normally on palpation, but if they are filled with blood, ascitic fluid, inflammatory exudate or tumor, the projecting lower part of the pocket can be felt. If doubt about the size or position of the uterus exists after the usual pelvic examination, the examiner may remove some of this doubt by examining the rectum and vagina simultaneously with one finger in the vagina and the other in the rectum (Fig. 7-4).

Dilated and thickened tubes are easily palpable. They are distinguishable from other tissues by their elongated shape which they retain even when enlar d

Leukorrhea is a very common complaint of women. The discharge may arise in any structure from any or no discoverable cause, from Bartholin's glands to the uterine tubes. The commonest causes of leukorrhea for which medical aid is sought are: normal physiologic variations in the amount of the vaginal secretions and unnecessary douching.

A severe vaginal irritation or burn, produced by a douche that was too hot, is followed by leukorrhea. A similar injury may be produced by a douche solution that is too strong or irritating. Infections by pyogenic bacteria, viruses (herpes simplex) and higher plant (yeast) and higher animal (trichomonas) parasites cause vaginal and cervical irritation and leukorrhea.

A yellow fluid discharge is often associated with vaginitis. If bubbles are present, the infection may be due to *Trichomonas vaginalis*. A trichomonad infested vaginal discharge has a foul, sour odor.

Watery, foul-smelling vaginal discharge, often colored, usually contains decomposed blood or organic material. This type of discharge was formerly said to be characteristic of cancer of the cervix, but it is far too common to have such a diagnostic import.

Foreign bodies in the vagina may be the cause of chronic leukorrhea. Objects of many different kinds have been recovered from the vagina, particularly in the insane and in sexual perverts and thieves. Foreign bodies tend to bury themselves in the vaginal wall and may cause considerable pain and discharge. They may slough through into the pelvic cavity, rectum or bladder. They may be so deeply imbedded in the vaginal walls that they can be removed only with the patient under anesthesia. Soda-pop bottles, or similar bottles, should be removed from the vagina by warming the bottle to dislodge the mucous membrane which has been sucked up in the neck of the bottle. Bottles are inserted immediately after removal of the bottle cap in order to use the contents for a contraceptive douche. Bottles become adherent by sucking in the vaginal mucous membrane when the contents of the bottle have been discharged.

Cyclic Changes in the Vaginal Epithelium. In brief, the vaginal mucosa during the lifetime goes through four cycles, each of which coincides with the current degree of ovarian activity. These four cycles are (1) postfetal or newborn, including the first week after birth; (2) infancy and childhood, from the postfetal period to puberty, (3) sexual maturity, puberty to menopause and (4) postmenopausal. The term senile vaginitis describes the postmenopausal change in the vaginal epithelium.

Vaginal Smears. Vaginal smears reflect these cyclic changes and perhaps the cyclic changes wrought by the monthly periods with fair accuracy when viewed by a histologist who is an expert in vaginal cellular morphology.

Tumors of the Vagina. ***Benign Tumors.*** *Inclusion cysts* are from some fragment of vaginal mucosa which is buried under the surface by a perineal laceration or operation. They are often situated on the posterior vaginal wall. Such cysts are difficult to visualize on the anterior wall except when the patient assumes the knee-chest position.

Inclusion cysts are small cysts less than 1 inch (2.5 cm.) in diameter. They are easily identified by the bluish color. As a rule these cysts cause little if any inconvenience.

Endometrial cysts are the result of cystic changes in ectopic endometrium. They are situated in the posterior fornix behind the cervix. These cysts are a part of the general manifestations of endometriosis elsewhere in the ovaries, uterine body or pelvic peritoneum.

Gartnerian cysts are formed by cystic dilatation of the remains (Gartner's duct) of the wolffian ducts. They are 1 or 2 cm. in diameter and are situated on the lateral or anterior walls of the vagina. Small cysts rarely cause symptoms; when large, they

The external type involves only the vaginal orifice, hymen, or terminal part of the vagina. Imperforate hymen is the commonest external vaginal atresia. In this type of lesion the menstrual blood accumulates in the vagina (hematocolpos) or in the uterine cavity (*hematometra*). *The collection of menstrual blood* forms a soft mass which bulges between the labia In these cases the lesion is due to defective development of the mullerian structures. The uterus and uterine tubes are normal

In some instances there may be no external bulging between the labia, but a cystic mass is palpable above the imperforate hymen In such a patient the atresia may involve the lower part of the vagina as well as the hymen

When there is an *internal absence or atresia of the vagina,* there is usually neither cervix nor uterus but the ovaries are present. The external genitalia, vaginal orifice and ovaries may appear normal The vaginal orifice is a shallow depression, rarely more than 1 inch (about 2.5 cm.) deep. It may be of normal width or may be very narrow. *In some instances, owing to efforts at coitus or dilatation, the vagina may be* about 2 inches (5 1 cm) deep

Internal absence or atresia of the vagina is symptomless until the age of menarche or until sexual intercourse is attempted In childhood it may be discovered accidentally by an observant mother or nurse or if accompanied by virilism The persistence of amenorrhea is the first symptom After marriage, the complaint is likely to be inability to have coitus (dyspareunia) or sterility The diagnosis is usually evident on examination.

Agglutination of the labia minord consists in an adhesion of the proximal edges of the labia The appearance of the anomaly is characteristic There is a bluish discoloration near the center of the membrane, formed over the vagina by the labia minora, indicating a space below it. The membrane is thin and is easily depressed by light touch with a blunt instrument

Hermaphroditism. In the human being *true hermaphroditism* is so rare that one should not expect to see it.

False hermaphrodites present the genital glands of one sex in an individual whose secondary sexual characters and external genitalia tend to resemble those of the opposite sex The internal genitalia can be those of either sex. There may be a doubling or mixing but often some of the parts are atrophic. The sex ratio of false hermaphrodites is 3 males to 1 female.

All grades of the *male pseudohermaphrodite* exist The general features are clearly or suggestively masculine, while the external genitalia are clearly or suggestively feminine In these, labial hernias often contain the testicles. After puberty the clitoris becomes large, it may approach the male penis in dimensions. The vagina is usually rudimentary or entirely absent It may open into the urethra. The internal genitalia of the male pseudohermaphrodite are often rudimentary.

In the female pseudohermaphrodite the gonads are ovaries The external genitalia are of either type, although enlargement of the clitoris is not the rule. The general external appearance, voice, bodily contour, distribution of hair, and temperament are usually female The internal genitalia consist of the ovaries, with the accessory male or female organs, when present, in varying degrees of development.

Hermaphrodites may be reared and trained as members of the sex opposite from their gonads During childhood this is serious; with the onset of puberty it is often tragic

Leukorrhea. The vaginal mucous membrane is protected by variable amounts [illegible] Excessive but normal increase of [illegible] near menstrual periods, at [illegible] he result of fatigue, excite- [illegible]

Childbirth injures the cervical tissues A lacerated cervix may become infected and never heal completely. A failure to heal of an obstetric injury, an infection or a surgical operation may cause stenosis of the cervix resulting in painful menstruation and sterility.

There may be no symptoms of chronic cervicitis. Often, however, there is leukorrhea. Rarely does chronic cervicitis give general symptoms

On examination there are areas of redness, eversion of the mucosa, scars, redundant granulations, and dilated glands—all of which are indications of cervical injury and infection

Chronic cervicitis which has followed an unhealed scar may have sharply defined borders or be diffuse to the reflection of the vagina, presenting the appearance of a chronic irritation There may be present yellowish or bluish cystic cervical glands. Some cervices are completely distorted by deep scars; they may be swollen,

Granulomatous Lesions of the Cervix. *Tuberculosis.* Incidences of tuberculosis as reported vary considerably. Counsellor and Collins recorded that the patients were 20 to 40 years of age in 73 per cent of their cases and stated that marriage and pregnancy are contributing factors in the disease

Tuberculosis of the cervix is primary if other foci are absent. The origin of primary cervical infections is by introduction from the outside This means of infection is exceedingly rare The lesions are secondary to foci in the lungs, the upper part of the genital tract, and the gastrointestinal tract

Different types of lesions occur The ulcerative type is most commonly seen and appears as a large region of deep ulceration with ragged undermined edges and a red, soft, easily bleeding, granulomatous base Ulcerative and papillary lesions may occur which are not grossly distinguishable from carcinoma.

The bleeding may be spotty or profuse. Often there is postcoital spotting. Leukorrhea is also a prominent symptom, the discharge is grayish yellow, thick, profuse and foul because of the destruction of tissue and the presence of caseous material Loss of weight, night sweats, anemia and weakness may be present, but generally these are due to the presence of tuberculosis elsewhere in the body. Pelvic pain is present with secondary infection or with tuberculous extension to the vagina, parametrium and upper part of the genital tract.

Clinically the diagnosis is seldom made unless *Mycobacterium tuberculosis* is found in the vagina or in the injected guinea pig The *Mycobacterium tuberculosis* cannot be differentiated from the *Smegma bacillus* in stained preparations.

Granuloma Inguinale. The cervix is one of the primary or secondary sites of granuloma inguinale

The specific etiologic agent is a microorganism which characteristically forms Donovan bodies (Donovania granulomatis), it has not been cultured and is pathogenic only for man The symptoms do not vary from those of carcinoma, but the youth of the patient is suggestive of a nonmalignant lesion.

On examination the early lesion appears as a shallow ulcerated area with well-defined edges and a diffuse, red, granulomatous base The advanced lesion consists of a large fungiform excrescence of soft, red, friable tissue replacing part or all of the cervix

The diagnosis depends on a demonstration of the Donovan body in smears, scrapings or a biopsy specimen Better results are obtained by the use of biopsy than from smears or scrapings Diagnosis is by no means a simple matter in chronic instances, since the characteristic monocytes may be scarce.

may interfere with sexual intercourse or with labor. The commonest complaint is the foul odor from the interference with normal discharge and drainage of urine

A large vaginal cyst in the anterior fornix may simulate a cystocele. A cystocele is emptied by urethral catheterization, whereas a cyst is not.

Papillomas and *polyps* are small sessile or pedunculated excrescences, often multiple, and are situated anywhere in the vagina.

Condylomas are polypoid growths that are of inflammatory origin Often they are due to syphilis, gonorrhea or other infection. Pregnancy and obesity favor the development of vaginal polyps and condylomas

Fibromas and *myomas* of the vaginal walls are rare. They may occupy any part of the vagina, and they occasionally attain large size. They are firm, movable tumors with a smooth surface

Granulation tissue may occur in vaginal scars Granulation tissue may arise in the margin of the vaginal scar after total hysterectomy These may be carcinomas if the patient has been operated on for carcinoma of the body of the uterus.

Malignant Tumors. The *carcinomas* of the vagina are commonly of secondary origin They occur in women past the menopause or older

Primary carcinomas may occupy any part of the vagina They are highly malignant, ulcerated, friable and indurated tumors which are fixed to the subjacent tissues. They invade the rectovaginal or vesicovaginal septum or urethra with the formation of fistula, urinary incontinence, infection, pain and incapacitation. They metastasize to the inguinal and pelvic lymph nodes. The earliest symptom is vaginal bleeding or discharge. On examination an indurated, fixed ulcerating lesion of the *vagina of an elderly woman is usually a carcinoma. Biopsy is diagnostic*

Secondary carcinomas of the vagina originate from carcinoma of the uterine cervix and uterus Anal and rectal carcinomas often extend to involve the vagina

Sarcomas of the vagina are rare They may be present in infants and in children, although no age group is entirely immune Vaginal sarcomas differ from benign polyps in being much harder, fixed to the deeper tissues, and invasive.

THE UTERINE CERVIX

The uterine cervix is the rounded knoblike end of the uterus which opens into the vagina It varies greatly in size and length in nulliparae It is about 1 inch (1 to 3 cm) in diameter. Occasionally it extends into the vagina as a cone-shaped projection 1⅕ to 1⅗ inches (3 to 4 cm) in length. The cervical canal opens into *the vagina by the external os and into the uterus by the internal os* The external os in nulliparae is round, but in those who have borne children or in those who have had deep cauterization it is an irregular transverse slit. The cervical canal is narrowed at both the internal os and the external os and is larger between, hence when instruments are passed into the uterus, they traverse with difficulty the external os and the internal os but pass readily between the two and into the uterine *cavity beyond*

The shape of the cervix and of the external os is so variable after childbirth that descriptions are impossible. Mutilations of the cervix worse than those of childbirth are rendered to it by surgeons in deeply cauterizing it or attempting to amputate it.

Chronic Cervical Irritation (Cervicitis) Many different kinds of organisms cause chronic infection of the cervix Of the bacteria those commonly present in chronic infections are the gonococcus, tubercle bacillus and various other pyogenic infectious agents. The cervix may be injured by fungi and *Trichomonas vaginalis*.

The glands of the cervix may become infected and if so they are often occluded An occluded infection in the cervix frequently becomes enclosed and chronic and persists.

grades of malignancy and for this reason length of survival usually but not always coincides with the grade of malignancy revealed by microscopic study.

There are no early or first *symptoms* of carcinoma of the cervix. There may be irregular bleeding and vaginal discharge In the life of a woman irregular bleeding and vaginal discharges are so common that she is forced to accept these as temporary inconveniences. Assuming that all agreed that in an attempt to detect all carcinomas of the cervix early enough for cure, biopsy be performed on every woman who has a vaginal discharge and irregular bleeding, it would soon be realized that these symptoms are not always present with carcinoma, for many women who have carcinoma of the cervix do not have bleeding until the late stages of the disease Some women who have died of carcinoma of the cervix were examined early by those skilled in the art of examination, and it was not until symptoms of widespread malignant disease were present that a diagnosis was made. This will continue to happen, despite all that can be done, until more is learned about this disease. It is impossible to estimate the stage of invasion by the duration or amount of bleeding Bleeding may occur only after coitus. Leukorrhea may come on early in the disease, it has no particular diagnostic significance even if the discharge is blood tinged Bloody leukorrhea is more significant of a benign polyp than of carcinoma. Pain in the course of cervical malignant disease is an unfavorable symptom, since it often indicates an extensive growth

On *examination* the earliest carcinoma of the cervix is superficial, limited to the epithelium or may be present in situ and thus it does not invade the subjacent tissue. In this stage the lesion cannot be identified by its gross appearance In the early carcinoma of the cervix, the malignant change may extend over the cervix or may remain localized near the cervical os For these reasons early carcinomas are discovered only during the microscopic examination of material removed for biopsy.

As the growth becomes invasive, the appearance of the cervix on examination may reveal that the tumor has grown externally, producing an ulcerating mass on the cervix In contrast to this the growth may have extended into the depth of the cervix leaving minimal surface changes However, as the tumor develops, it extends to the surrounding structures The degree of involvement of the extracervical tissues is important both diagnostically and therapeutically.

On palpation there often is extension into the broad ligament and the bladder, and posterior extension along the uterosacral ligaments to the sacrum, the rectum and the sacral nerve roots The regional lymph nodes are involved in the following order of frequency, hypogastric, obturator, ureteral and external iliac Lymph-node involvement is always indicative of extensive malignant disease

The foregoing findings on examination are clearly identified in the *Annual Report on the Results of Radiotherapy in Carcinoma of the Uterine Cervix* (1952) (the so-called *League of Nations' Classification*) The 12 representatives meeting in session on the occasion of the International and Fourth American Congress of Obstetrics and Gynecology in May, 1950, agreed that the staging of carcinoma of the cervix should read as follows (quoted by permission of the Editorial Committee)

Stage O Carcinoma in situ—also known as pre-invasive carcinoma, intra-epithelial carcinoma—and similar conditions

Stage I The carcinoma is strictly confined to the cervix

Stage II The carcinoma extends beyond the cervix but has not reached the pelvic wall The carcinoma involves the vagina but not the lower third

Stage III The carcinoma has reached the pelvic wall. (On rectal examination no "cancer-free" space is found between the tumour and the pelvic wall.) The carcinoma involves the lower third of the vagina.

Stage IV The carcinoma involves the bladder or the rectum, or both, or has extended beyond the limits previously described.

Syphilis. A chancre of the cervix in the stage of recognizable development appears as a deep, funnel-shaped sore with thickened, rounded edges which slope down to a smooth base

The macules of secondary syphilis of the uterine cervix appear as grayish-white, slightly elevated areas. Large macules or confluences of smaller ones are termed mucous patches. The erosion of the mucous patch is covered with a pinkish or a grayish exudate which may contain spirochetes. Secondary syphilitic ulcers are associated with yellow, mucopurulent vaginal discharge.

The gumma undergoes ulceration and necrosis; or occasionally, tissue prolifera-tion occurs so that a fungating, soft mass replaces most or all of the cervix.

The diagnosis of primary and secondary lesions depends on the finding of *Treponema pallidum* by darkfield examination, since results of serologic tests are not always positive until three weeks after the initial infection. The tertiary lesion (gumma) is diagnosed by biopsy and positive serologic tests.

Chancroid. Chancroid of the cervix is rare Symptoms include soreness in the lower part of the abdomen, grayish vaginal discharge and burning and pain in the vagina. On examination there may or may not be ulcers of the external genitalia and inguinal lymphadenopathy. Pronounced vaginal tenderness is present The cervix appears to be red and edematous with one or more round, firm, punched-out, ulcerated lesions on the portio vaginalis. The ulceration may be covered with an easily removable whitish exudate. Diagnosis is established by smear, culture, skin test and biopsy (see p. 410).

Tumors of the Cervix. Benign Tumors. *Cervical polyps* usually occur in adult women, rarely before the age of 30 years For practical purposes cervical polyps are not malignant, but malignant changes occur frequently enough to require histologic examination of every polyp that is removed.

Cervical polyps are among the commonest causes of intermenstrual bleeding They may cause leukorrhea and may produce sterility Some cervical polyps, if large, can be felt on palpation On visualization a cervical polyp appears more reddened and of a deeper color than the cervix. It usually projects from the cervical os and can be moved about by means of a cotton swab. These polyps often bleed easily when traumatized .They are differentiated from prolapse of the mucous membrane of the cervix by their mobility and microscopic structure.

Since most myomas develop in the body of the uterus, *cervical myomas* are rare and they seldom are diagnosed prior to operation.

Malignant Tumors. *Carcinomas* of the uterine cervix usually occur in women who have borne children and who are between the ages of 40 and 55 years They develop in the regions of chronic irritation, epithelial erosion, unhealed laceration and in polyps.

Macklin studied the morbid heredity in cervical cancer, and her conclusions leave little doubt that in certain families, but only in certain families, does heredity seem to play a part in the incidence of carcinoma Jewish women rarely, if ever, have malignant cervical polyps and cervical carcinoma

Carcinoma of the external cervix of the uterus arises from the vaginal portion including the transition zone at the external os Carcinoma of the endocervix arises between the internal os and the external os of the cervix

Carcinoma of the cervix has offered difficulties in classification. Cervical carcinomas are chiefly of the squamous cell variety A few adenocarcinomas are encountered Either the squamous cell carcinoma or the adenocarcinoma can be classified on the basis of anaplasia. Broders' classification is based on anaplasia In this grouping grade 1 [illegible] malignant, show the greatest tendency [illegible] and grade 3 carcinomas show greater [illegible]ile those of grade 4 are the most ana-[illegible]nt It is recognized that most cervical carcinomas are mixed tumors, [illegible]ly contain cells of various types and

The *diagnosis* is established by biopsy. If the cervix is chronically irritated or ulcerated in middle-aged women, and in some young women, even if there are no symptoms, cancer is suspected

Meigs and Jaffe found in their analysis of the survival rates of patients undergoing irradiation that most of the deaths occur in the first 2 years and that most patients without obvious disease at the end of 2 years have a good chance for recovery. Kimbrough and Tompkins found that 23 3 per cent of the patients survived 5 or more years and that 18.7 per cent of the original group lived more than 10 years after treatment

Bleeding from the cervical stump is a serious symptom, for it is most frequently due to carcinoma If cervical carcinoma appears within a year after hysterectomy, it was probably present at the time of the operation Biopsy is diagnostic.

Many have expressed the belief that carcinoma of the cervix in *pregnant women* progresses more rapidly than in older nonpregnant women. It should be realized that a cervical carcinoma tends to cause abortion. The presence of carcinoma generally is an indication for abortion The religious beliefs of the patient should be respected after the stark facts have been presented to her.

THE UTERUS

Attachments of the Uterus In addition to being attached to the vagina, the uterus has certain folds or ligaments which pass from it to the surrounding parts Anteriorly the peritoneum is reflected from the uterus at the level of the internal os to the bladder, forming the *uterovesical fold*. Posteriorly the peritoneum descends from the uterus over the posterior surface of the upper portion of the vagina for about ½ inch (1 3 cm) and thence onto the rectum, constituting the *rectovaginal* or *recto-uterine fold*. The deep pouch so formed is called *Douglas' pouch* On each side are three ligaments, of which the *broad ligament* is the largest and most important The two broad ligaments and the uterus form a diaphragm which extends from one side of the pelvis directly across to the other, thus dividing it into anterior and posterior compartments

At its pelvic attachment the broad ligament widens out, having the round ligament as its anterior edge and the *infundibulopelvic* or *suspensory ligament* of the ovary as its posterior edge Immediately posteriorly is the *uterosacral ligament* (recto-uterine), it runs from the uterus backward and contains muscular and fibrous tissue, the muscular tissue goes to the rectal wall, while the fibrous goes to be attached to the second and third sacral vertebrae This ligament on each side forms the outer border of Douglas' pouch These ligaments may become sensitive if the so-called *uterosacral syndrome* ensues

The round ligament leaves the cornu of the uterus just below and anterior to the uterine tube, and passes outward, forward, and slightly upward to reach the internal inguinal ring and canal, through which it passes to end in the subcutaneous tissue and skin of the labium majus pudendi.

Congenital Malformations. See malformations of the vagina, page 449.

Chronic Subinvolution. Chronic subinvolution of the uterus occurs after childbirth, most frequently in women between 35 and 45 years of age However, the condition may appear in any woman who has had a baby

The pregnant uterus contains an increased amount of elastic tissue in its walls and in the enlarged blood vessels In the course of normal puerperal involution of the uterus the increased amount of elastic tissue in the myometrium and vessel walls is absorbed and new vessels of smaller caliber are formed When this elastic tissue is not properly absorbed, degenerative changes follow. The connective tissues undergo liquefaction and hyalinization and become edematous because of failure of re-establishment of an efficient circulation The uterus remains enlarged

The common symptoms are profuse menstruation, intermenstrual bleeding, leukorrhea and pelvic pain. On examination the uterine body is diffusely and symmetrically enlarged An exact diagnosis is made only by microscopic study of the excised uterus

This classification was adopted by the three American societies and recommended by the Subcommittee of the World Health Organization on the Registration of Cases of Cancer and their Statistical Presentation.

In stage-grouping the following general rules should be observed:

When allocating a case to a stage nothing but facts revealed by examination should be taken in account.

The stage of each case should be decided at examination prior to treatment and this classification should remain. The classification may be postponed quite exceptionally and the reasons stated.

When it is doubtful to which stage a given case is to be allocated, the earlier stage should be chosen

The fact that a single case presents two or more of the conditions which characterize a particular stage does not affect the staging.

The Editorial Committee recognizes that the classification of 1950 represents a large step forward but considers that in regard to the uniform presentation of statistics on carcinoma of the cervix, there are a few points which need further explanation.

1 The type of case to be allocated to Stage O should be strictly defined. This must be deferred until further experience on the subject has been accumulated Pending such definitions the collaborators are earnestly requested to allocate to Stage I only such cases in which the presence of an invasive carcinoma is beyond doubt

2. The signs which characterize involvement of the bladder should be defined Cases in which on cystoscopy there is no fistula, no ulcerating tumour and no tuberculi visible but which show bullous oedema or ridges and furrows are difficult to classify

The Editorial Committee suggests that.

(a) A bullous oedema should only be considered as a sign of involvement of the bladder if the diagnosis is microscopically verified, (b) Ridges and furrows should only be interpreted as a sign of involvement of the bladder if they remain during palposcopy This method of examination implies coincident cystoscopy and digital examination of the bladder trigone by rectal palpation Where there is no carcinomatous involvement of the bladder wall the ridges and furrows will disappear when the trigone is lifted up The method has not previously been described It has been used for many years at the Radiumhemmet, Stockholm, as a routine examination in all cases of cervical carcinoma

3 According to the classification of 1950, a case should be allotted to Stage II if the involvement of the parametrium "has not reached the pelvic wall," and to Stage III if it "has reached the pelvic wall" The definitions of 1937 state "has not invaded the pelvic wall" and "has invaded the pelvic wall" The Editorial Committee is of the opinion that it should be seriously considered at a future revision of the definitions which of these two versions is more suitable

The study of *vaginal smears* as a means of early diagnosis of cervical or uterine cancer was advocated and practiced by Papanicolaou Cervical cancer is revealed in vaginal smears by the appearance of characteristic cells derived from the superficial layers of the tumor, which undergo continual desquamation These cells show great variety of form and size, much greater than that seen in sections of the tumor. The most characteristic feature of the abnormal cells is the atypical form and structure of their nuclei and vacuolization of the cytoplasm A commonly found, characteristic cell type is an extremely elongated one resembling a smooth muscle fiber. Erythrocytes are generally found in large numbers. Block warned, however, that a positive diagnosis from a vaginal smear does not indicate immediate radical intervention or irradiation but rather that confirmatory biopsies of the cervix or endometrium should be performed.

The commonest cause of spontaneous abortion is the intrinsic factor comprising malformations of the fertilized ovum.

There are two groups of *extrinsic* factors which may precipitate spontaneous abortions. These are the environmental factors external to the body and the factor of disease within the body. For instance, it is said that women during the first two or three months of gestation should avoid excesses of drugs, alcohol, cold, heat, trauma, exertion, infections and local stimulation.

The diseases within the body which are potent in the production of spontaneous abortion are pyogenic infections, gonorrhea and tuberculosis. Tumors such as myomas and ovarian tumors may cause abortion. Uterine retroflexion, laceration and injury to the cervix, repeated pregnancies, uterine hyperirritability, congenital malformations and constitutional diseases all may precipitate spontaneous abortion Diabetes may be associated with abortion. If a woman who has an endocrinopathy should conceive, the pregnancy is likely to terminate in spontaneous abortion.

A general anesthetic drug, quinine and castor oil, turpentine, ergot, irradiation and trauma may cause spontaneous abortion All sorts of herbs, and folk medicine consisting of pastes and solutions, are used for intra-uterine injection to produce spontaneous abortion or to bring on the period.

In regard to physical exercise, it is observed that a healthy ovum in the uterus of a hardworking woman is not dislodged by any sort of ordinary, or even laborious, task performed by her. A diagnostician is loath to attribute abortion to many of the overemphasized inconsequential causes.

On the basis of the relative completion of the process, abortions are termed threatened, inevitable, complete, incomplete and missed. The symptoms, diagnostic findings and therapy vary with the type that is present.

In a *threatened abortion* the bleeding is slight and the pain, if any, is only moderate It is a discomfort in the lower part of the abdomen. The cervix is not dilated

In *inevitable abortion* the cervix is dilated, membranes are often ruptured, and bleeding is profuse or has persisted despite rest The uterine contractions return as soon as opiates and rest are discontinued In such cases the process is hastened to completion.

In *incomplete abortion* the uterus has been partially emptied spontaneously or intentionally If there are no manifestations of infection, it is best to complete the abortion All abortions should be considered to be infected

Habitual abortion has possible endocrine, gynecologic and urologic associations. However, in many instances no disturbances to account for an abortion can be demonstrated in any of these categories

In a *missed abortion* the membranes and the fetus are still in place. The fetus is dead There is amenorrhea, followed by slight bleeding, with some pelvic discomfort. The uterus does not increase in size as the pregnancy lengthens Soon toxic or absorptive phenomena, malaise, headache, nervousness and apprehension supervene. The absence of a positive reaction to Friedman and Aschheim-Zondek tests or one of these tests for pregnancy would confirm the diagnosis

Therapeutic (Induced) Abortion. A therapeutic abortion is performed as a part of the treatment for some disorder that concerns the mother or the fetus. The indications for a therapeutic abortion vary so widely that only one rule can be given for the diagnostician to follow This rule is never to advise a therapeutic abortion on data supplied by anyone else. Weigh all the findings obtained as the result of personally conducted examinations and from these data make a decision. It is well to remember that a therapeutic abortion may carry some risk to the patient, depending on her physical condition.

Rape resulting in pregnancy is an indication for abortion (see p 479).

Hypertrophy. There are women who have diffuse enlargement of the uterus as the result of hypertrophy of the muscle. In view of the presence of endometrial hyperplasia in all of these cases, it is suggested that the uterine enlargement may be in a measure due to hyperestrogenism

The symptoms are menorrhagia, metrorrhagia, leukorrhea and pelvic pain On examination the uterus is diffusely enlarged. Microscopic study of the uterus establishes the diagnosis.

Primary Dysmenorrhea. Dysmenorrhea is present in approximately one third of menstruating women. It commences with the menarche. The distress starts the day prior to or with the menstrual flow and consists of cramps in the lower part of the abdomen which may or may not be associated with backache, headache, nausea and vomiting It persists through the first or second days of the flow. There may be prodromal irritability, backache, headache and gastrointestinal upsets The dysmenorrhea may partially or wholly cease after the birth of the first child. After the age of 30 years in the nulliparous woman the dysmenorrhea may become irregular and of lessened intensity.

It is agreed that there is no consistent anatomic lesion in patients who suffer from primary dysmenorrhea It is not due directly or indirectly to a retroverted, anteflexed or infantile uterus, cystic ovaries, presacral neuritis, defective uterine musculature or disturbed innervation

The pain experienced is due to uterine contractions. This point of view is confirmed by the experimental work of Moir and Bickers, working separately, and of Randall and Odell. Ovulation is a necessary precursor to painful menses. The presence of secretory endometrium (suction biopsy) as recorded by Randall and Odell and Sturgis and Albright renders this premise certain. Ovulation is prevented by diethylstilbestrol and thus there is no development of secretory endometrium, and painless menstruation ensues.

The presence of backache, nausea, vomiting and headache can hardly be explained on an organic basis. Premenstrual tension, as evidenced by abdominal pain, irritability, headache, backache and nervousness, is on a psychogenic basis. These patients should be assured that they are absolutely normal and should receive an explanation in simple terms of the basic physiology of menstrual distress Some relief of pain can be obtained with simple analgesics, particularly after the patient realizes the nature of her complaint

Infections of the Uterus. Infections of the endometrium are usually a part of a diffuse genital infection. Endometritis following childbirth is a serious condition which may leave permanent sequelae Tuberculosis, trauma, foreign bodies and tumors may cause endometritis

In the acute stages of puerperal sepsis the uterine wall may be severely infected and if uterine drainage is poor, a chronic metritis may persist indefinitely.

Chronic Metritis. *The condition occurs in both parous and nulliparous women.* Often there is an associated inflammatory lesion in the uterine tubes Occasionally chronic endometritis without obvious lesions of the appendages may be encountered. Chronic subinvolution and chronic metritis may occur in the same uterus. In this event there are the pathologic changes that mark both these conditions The symptoms are menorrhagia, metrorrhagia, leukorrhea and pelvic pain. Examination reveals an enlarged uterus Diagnosis is made by microscopic examination of the uterus.

Abortion. For diagnostic purposes all abortions are either spontaneous or induced

[illegible] may [illegible] *rinsic*

factors

the uterus is enlarged and usually smooth in outline. If menstrual bleeding has been excessive, there is anemia.

The diagnosis is made by biopsy of uterine tissue. The history and the examination may in some instances be almost conclusive. In others, not even a suggestion of the true condition will be evident. Myoma, chronic subinvolution of the uterus, and adenocarcinoma of the endometrium are differentiated by endometrial biopsy.

External Endometriosis. By definition, in external endometriosis the endometrium has been transplanted or has originated outside of the uterus (Fig 7-5). An internal endometriosis also may be present and vice versa

The theories of the origin of external endometriosis are (1) embryonic rests, (2) metaplasia and (3) transportation of either uterine or tubal epithelium

The theory of embryonic rests of cells derives its plausibility from the fact that epithelium of the uterine tubes and uterus and the germinal epithelium of the ovary all have a common origin in the celomic epithelium In the ultimate distribution and differentiation of the celomic epithelium it is postulated that it may be scattered from the umbilicus to the knees

As the result of irritation, inflammation or hormonal disturbances the pelvic peritoneum undergoes metaplasia, changing into columnar epithelium and forming glands that resemble endometrium or tubal mucosa in appearance and function.

Adult epithelium, tubal or uterine, may be transported to the ectopic sites by the lymphatics, veins and peritoneum, or by surgical operation. As the lesions progress, rupturing of the cysts gives rise to implants throughout the pelvis. The fluid from an endometrial cyst is irritating and produces peritoneal reaction with subsequent adhesions cementing the pelvic viscera together. The lesions of endometriosis are black or brown, puckered or cystic areas. The lesions are often situated on the undersurface of the ovary and the adjacent part of the broad ligament, and on the posterior surface of the cervix along the attachment of the uterosacral ligaments.

Endometrial tissue in or near the umbilicus of the abdominal wall appears as bluish cysts which swell and which may discharge blood with each menstrual period When the lesion is found in an abdominal scar, there is a history of some uterine or tubal operation

There have accumulated reports of many instances of endometrial tissue being present in the sigmoid colon Many of the patients who have these sigmoid lesions have suggestive histories and findings of endometriosis only in retrospect after the diagnosis is established by biopsy.

The presence of endometrial tissue in the bladder causes frequent and painful micturition

After the menopause, whether induced by surgical intervention, irradiation or nature, endometrial tumors retrogress

Many women who have endometriosis have no symptoms referable to the pelvic [illegible]

[illegible] significant.

On examination, if the external lesion, like a vaginal or umbilical cyst, can be seen, it is almost diagnostic in appearance, but lesions of this type are rare. When cysts are brought into view by means of the vaginal speculum, artificial light can be caused to reflect and they shine as do the eyes of an animal at night.

On palpation the significant findings are in the adnexa. About the cervix and in the rectovaginal septum hard nodular, rather fixed lesions are often palpable The ovaries are fixed and enlarged and vary in tenderness The uterus is often retroflexed, and in women more than 35 years old is often myomatous

A definite diagnosis is established by biopsy. However, in a young woman

Endometriosis (Adenomyoma, Adenomyosis and Endometrioma). When uterine or tubal mucosa is situated anywhere except in its normal position in the tubes and the uterus, the condition is termed endometriosis. Endometriosis may be internal (uterine) or external (extra-uterine)

The usual and unusual distributions of the lesions are shown in Figure 7-5. The lesions often are multiple, occurring in more than one organ. The incidence of endometriosis is not known but the disease is common.

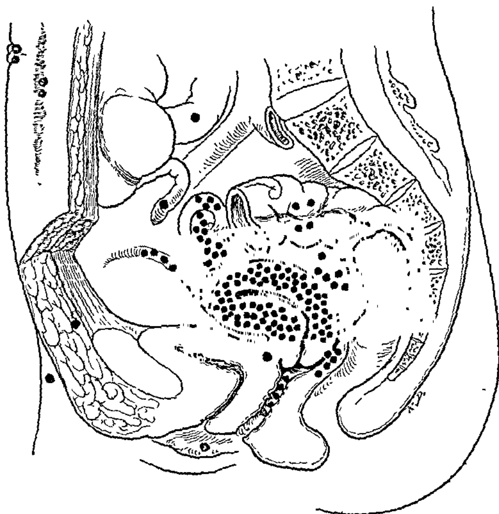

Fig 7-5 Endometriosis The commonest sites of occurrence are indicated.

Internal Endometriosis. When endometrium is found disseminated throughout the uterine wall, the condition is termed internal endometriosis In internal endometriosis the epithelial tissue is continuous with the endometrium which lines the uterine cavity.

The ectopic endometrium is scattered throughout a part or all of the uterine wall When the epithelial elements are collected into nodules, the condition is termed endometrioma When these epithelial elements are in muscle tissue they are termed adenomyoma.

The first symptom of uterine endometri... d of infertility followed by symptoms of pressure of th... rual irregularities The menstr... and menorrhagia The ... by intense pain On pelvic examination

advanced pregnancy is detected by the presence of fetal movements and fetal heart sounds, and by roentgenologic evidence

Endometrial cysts, chocolate cysts and tubo-ovarian masses simulate uterine myoma and are often associated with fibroid tumors of the uterus. Small asymptomatic myomas do not require treatment. Large tumors should be removed

Malignant Tumors. *Carcinoma of the endometrium* occurs more frequently in women after the menopause than in younger women. The first symptom is frequently postmenopausal bleeding If the tumor occurs prior to the menopause, intermenstrual bleeding and profuse menstruation occur In the beginning the bleeding is slight and transitory and may never be more than an intermittent brownish or bloody tinge in leukorrhea which has been present for a long time Leukorrhea is not significant. As the growth advances, however, the discharge may become more profuse and foul. On examination the uterus is somewhat enlarged and soft The diagnosis is made by microscopic examination of the endometrium.

Papanicolaou became aware that carcinoma of the fundus of the uterus as well as carcinoma of the cervix (see p. 456) are to some extent exfoliative lesions in the sense that cells at the free surface of the growth tend to become dislodged and subsequently to find their way into the vagina He developed a method for collecting the cellular debris from the uterus as well as the cervix, which is smeared on glass slides and stained in a particular way so that the various components may be studied The method is simple and may be applied to large numbers of women Papanicolaou states that cells pathognomonic of cervical and fundal carcinoma can be definitely recognized. The interpretation of smears calls for an intimate knowledge of the cytologic characteristics of the vaginal fluid

Malignant cells will not always be present in every smear from cases of cancer even though the tumor may be very large and clinically obvious The method seems to be used as an adjunct rather than a substitute for biopsy and histologic examination

Primary sarcoma of the uterus is very rare When present, it occurs in the walls of the uterus

Secondary sarcoma in a myoma is rare The frequency of sarcomatous changes in myomas is not known

When sarcoma is present in a myoma, there is rapid growth, and often pain. These rapidly growing myomas may occur after the menopause, when myomas should decrease in size The examination reveals a tumor that feels like a myoma

The diagnosis is not made until the tumor is examined histologically.

Tumors of the Chorion. Benign Tumors. A *hydatid mole* (hydatidiform mole, vesicular mole) is a rare lesion When it occurs, it follows pregnancy by several months to 2 or 3 years

The hydatid mole may invade the entire thickness of the uterus and perforate the peritoneum. This may produce peritonitis and intraperitoneal hemorrhage.

Embolic transplantation of fragments of hydatid mole tissue has been observed in the vaginal walls, the parametrium and the lungs Transplantation of this tissue does not indicate metastasis, as is observed in malignant disease A certain percentage of benign hydatid moles, however, become malignant chorionepitheliomas.

Intermittent uterine bleeding is a symptom There are periods of active bleeding, between which a serosanguineous discharge appears Soon there are pain in the lower part of the abdomen, weakness, and often anemia. Abortion is frequent The abortion is accompanied by hemorrhage which is usually profuse, prolonged and sometimes fatal because uterine muscle may be invaded and unable to contract vigorously.

On examination the uterus seems to be pregnant, although there are no evidence of the fetus, no fetal heart beats, no fetal movements, and no fetal shadow on roentgenographic examination Reactions to the Friedman and the Aschheim-

who gives no history of a pelvic infection and who has hard nodular lesions about the cervix and retrovaginal tissues with fixation of the ovaries in association with sterility and progressive dysmenorrhea, the diagnosis is reasonably certain to be endometriosis.

In the differential diagnosis consideration is given to (1) chronic salpingitis, (2) uterine myomas, (3) the presence of ureteral renal and ureteral stones and (4) lesions of the pelvic colon.

Endometriosis of the rectovaginal septum is distinguished from carcinoma by the presence of endometriosis elsewhere, the absence of metastasis and presence of endometrial cysts behind the cervix.

Uterine Neoplasms. ***Benign Tumors.*** The myomas, the fibromas or the myofibromas comprise the major part of the important benign tumors of the uterus.

A *uterine myoma* is a benign tumor composed of smooth muscle and connective tissue. This type of tumor is known also as fibromyoma, myofibroma, leiomyoma and fibroma The etiology is unknown.

Myomas are common in women of all races. They are most frequently found in women from 40 to 45 years of age, although they may occur in young women; the age limits are usually given as from 30 to 55 years Uterine myomas have a wide range of size, situation and shape.

Myomas are often referred to according to their situation; for instance as intramural, subperitoneal or submucous The large myomas show hyaline and cystic changes Suppuration and formation of abscess are rare Incomplete or complete calcification may occur. Intramural myomas may cause intramenstrual bleeding

Generally uterine myomas are symptomless. Symptoms do occur, however, and when present are due to changes within the myomas, to degenerations, to unfavorable anatomic relationships and to submucous development The common symptoms are pain, tumor, menorrhagia and sterility The patient may first palpate the mass, which may reach the umbilicus before there are symptoms. More frequently, however, a large myoma is sensitive to pressure There is pain which is due to a complicating adnexal or pelvic disease The pain may be a sensation of pressure, or dysmenorrhea, dysuria, painful defecation or a sacral backache Occasionally it is referred down the thighs or up into the ureteral or the renal regions

Dysmenorrhea is often associated with profuse menstrual bleeding.

On routine pelvic examination of women who have attained the late thirties or more, a few of them, by no means all, will have one or more myomas. The myomas are an insensitive uterine enlargement which is nodular, hard and movable The masses are usually round and multiple and vary in size up to those which occupy the entire abdomen. A large myoma which has undergone degeneration may be soft and cystic and cannot be distinguished on palpation from a normally pregnant uterus or an ovarian cyst Small myomas which are clustered about the uterus cannot be differentiated by physical means from an endometriosis

Anemia may result from the menorrhagia and may be serious Occasionally anemia is encountered in women who have myomas but who have not had bleeding These anemias are the same as those present in many women who menstruate These anemias can be corrected by the administration of iron, or the patients may spontaneously recover after hysterectomy

In diagnosis a tumor situated in or adherent to the uterus without symptoms is usually a myoma, and such a tumor associated with the forementioned symptoms is nearly always a myoma.

A soft myoma, causing symmetric enlargement of the uterus, is indistinguishable on palpation from a normal pregnant uterus The Aschheim-Zondek, Friedman and frog tests are the most certain methods of detecting an early pregnancy. A more

LOCALIZATION. The vaginal epithelium in children, in women during pregnancy, and in senile women is thin, its secretions are but slightly acid, and it offers slight resistance to the gonococci

The vaginal epithelium of the adult nonpregnant woman is thicker, produces a stronger acid secretion and is resistant to gonococci In young women gonorrheal vaginitis is usually slight and transient and there is no localization in the vagina and cervix as is observed in girls and in aged or pregnant women. Gonorrheal endometritis is generally transitory

In the periurethral ducts of Skene and the vulvovaginal and cervical glands the gonococcus grows and produces its full effects There are swelling and inflammation which occlude the openings to the ducts and result in acute, chronic, deep and permanent infections, and formation of abscesses and cicatrices. If the tubal openings are closed by the inflammation, pyosalpinx and hydrosalpinx are often present. Sterility, recurring exacerbations of the infection, pelvic peritonitis and pelvic abscess are serious complications resulting from gonorrheal salpingitis. If the tubes remain open, as they usually do, no serious sequelae are observed. As a rule, a localized pelvic peritonitis accompanies salpingitis

Ophthalmia, when it ocurs, is usually a direct contamination transmitted from the genital tract to the eyes by the hands.

Among metastatic infections (lymphogenous or hematogenous) are adenitis, septicemia, endocarditis, hepatitis, arthritis, periostitis, osteomyelitis, tenosynovitis and dermatitis All of these are described under their respective headings elsewhere in this text.

The chronic foci of infections in the external genitalia are the cervical glands and epithelium, Bartholin's glands and Skene's glands In children and in the aged or the pregnant woman the vagina is the focus of chronic infection

The infection becomes chronic by closing or constricting the ducts of the glands. This interferes with the escape of infectious material for long periods of time The material which collects thus may form an abscess. In time, if the abscess resolves, the fluid in the occluded gland may be clear or translucent, the gland being changed into a cyst This cyst in turn may become an acute pyogenic abscess or may remain a cyst. The size of the abscess or cyst varies, occasionally it attains several centimeters in diameter. The orifices of Bartholin's glands are occasionally just visible as red spots (gonococcal maculae) In ancient infections Bartholin's glands remain indurated

SYMPTOMS The symptoms of gonorrhea are classed as acute and chronic. Many women during acute gonorrhea notice a slight burning on urination, perhaps an increase of a vaginal discharge, and discomfort. These symptoms are experienced frequently by most women, however, and are usually inconsequential. Other women have had no unusual symptoms and are unaware that anything is wrong until salpingitis develops A few women have acute symptoms, comprising definite burning on urination, frequency, vaginal pain, itching and leukorrhea

Chronic gonorrhea of the external genitalia of women, as a rule, does not cause symptoms In a few women, however, the symptoms of chronic gonorrhea of the internal genitalia never seem to subside There are leukorrhea and urinary symptoms and a continuance of the active and infectious disease. In a few cases cysts of Bartholin's glands may cause local inconvenience; recurring abscesses of Bartholin's glands cause local pain, swelling and redness, recurrent burning on urination, and cystitis Sterility may be the complaint caused by a gonorrheal cervicitis However, sterility does not often occur, for many women who have chronic gonorrhea bear children normally.

After long periods without symptoms, there may be exacerbation of the infection, abscess of Bartholin's glands, cystitis, salpingitis or arthritis.

EXAMINATION In the acute stage there are general swelling and redness of the genital mucosa accompanied with a purulent discharge from the urethra and cervix Results of examination of those who have chronic gonorrhea may be negative, or there may be pus expressed from Skene's glands.

Zondek tests are often stronger than normal in a live hydatid. Diagnosis is established by microscopic examination of the products of uterine curettage

Malignant Tumors. Chorionepithelioma, a rare complication of a rare disease, the hydatid mole, may follow abortion, full term pregnancy or ectopic pregnancy, or may occur as a tumor of the testicle. In men it exhibits the same degree of malignancy and high urinary titer of hormones (Aschheim-Zondek, Friedman and frog tests) that are observed in women. Metastasis in chorionepithelioma is widespread and early The common sites of metastatic lesions are the lungs, vagina and brain

The appearance of a vaginal lesion may be the first indication of a chorionepithelioma. After an abortion, full term pregnancy or ectopic gestation repeated or continued bleeding usually is due to retained placental or decidual tissue, and curettage is performed If bleeding recurs after curettage and is accompanied by a rising titer of chorionic hormones in the urine, the diagnosis of chorionepithelioma can be made from these symptoms. The diagnosis is established by microscopic examination of a metastatic nodule or the primary tumor.

THE UTERINE (FALLOPIAN) TUBES

A normal uterine tube is about 4½ inches (11.4 cm) long and runs in the broad ligament along its top or free edge from the uterus to the ovary

CONGENITAL MALFORMATIONS The uterine tubes develop from the mullerian ducts, along with the uterus and the upper part of the vagina In a grave defect, such as complete nonunion or marked inhibition in the development of the mullerian ducts, the uterine tubes are likely to be rudimentary In the absence of the uterus, or in the presence of completely double uterus or rudimentary uterus, the uterine tubes are hindered from their normal development.

Double Fimbriae This condition is not rare and is inconsequential, causing no symptoms

Congenital Occlusion. Congenital occlusion of the uterine tubes is accompanied by retarded uterine development (hypoplasia).

Absence of Uterine Tube This malformation is rare. It is usually due to aplasia of an entire mullerian duct and is evident in the resulting type of uterine deformity, uterus unicornis. In this condition the entire uterus, cervix and upper part of the vagina are formed from one mullerian duct.

Absence of one mullerian duct, with consequent absence of one tube, may be accompanied by absence of the homolateral ovary and kidney.

Rudimentary Uterine Tube. This is also rare except in the presence of rudimentary development of the whole mullerian duct

Infections. Infections, termed salpingitis, are the most important lesions of the uterine tubes. They are significant, not only because of their effect on the patient's health, but also because they frequently produce permanent tubal occlusion and sterility

The inflammatory diseases of the uterine tubes conform to certain definite types, of which the commonest are those due to (1) gonorrhea, (2) pelvic abscesses, (3) tuberculosis, (4) puerperal infections and (5) appendicitis Other less common varieties are associated with systemic infection. Not all tubal infections are discussed here.

1. ***Gonorrhea.*** Gonorrhea is primarily an infection of the mucous membrane of the urogenital tract of men, women, and girl children. In women of the child-bearing age the characteristic type of infection occurs in the *uterine tube* It is for this reason that gonorrhea in women is discussed with diseases of the uterine tubes, the epithelium of the uterine tubes offers little resistance to the gonococci.

Since the advent of chemotherapy and antibiotic therapy the following sequence of events occurs only when the infection exists without the benefit of the use of these drugs.

OCALIZATION. The vaginal epithelium in children, in women during pregnancy, in senile women is thin, its secretions are but slightly acid, and it offers slight ance to the gonococci

he vaginal epithelium of the adult nonpregnant woman is thicker, produces a ger acid secretion and is resistant to gonococci In young women gonorrheal itis is usually slight and transient and there is no localization in the vagina and x as is observed in girls and in aged or pregnant women Gonorrheal endometritis nerally transitory

n the periurethral ducts of Skene and the vulvovaginal and cervical glands the coccus grows and produces its full effects There are swelling and inflammation h occlude the openings to the ducts and result in acute, chronic, deep and perma- infections, and formation of abscesses and cicatrices. If the tubal openings are d by the inflammation, pyosalpinx and hydrosalpinx are often present Sterility, ring exacerbations of the infection, pelvic peritonitis and pelvic abscess are serious plications resulting from gonorrheal salpingitis If the tubes remain open, as they lly do, no serious sequelae are observed. As a rule, a localized pelvic peritonitis mpanies salpingitis

Ophthalmia, when it ocurs, is usually a direct contamination transmitted from the al tract to the eyes by the hands

Among metastatic infections (lymphogenous or hematogenous) are adenitis, icemia, endocarditis, hepatitis, arthritis, periostitis, osteomyelitis, tenosynovitis dermatitis All of these are described under their respective headings elsewhere is text.

The chronic foci of infections in the external genitalia are the cervical glands and elium, Bartholin's glands and Skene's glands. In children and in the aged or the nant woman the vagina is the focus of chronic infection.

The infection becomes chronic by closing or constricting the ducts of the glands. interferes with the escape of infectious material for long periods of time The mate- which collects thus may form an abscess In time, if the abscess resolves, the fluid e occluded gland may be clear or translucent, the gland being changed into a cyst. cyst in turn may become an acute pyogenic abscess or may remain a cyst. The of the abscess or cyst varies, occasionally it attains several centimeters in diameter. orifices of Bartholin's glands are occasionally just visible as red spots (gonococcal ulae) In ancient infections Bartholin's glands remain indurated

SYMPTOMS The symptoms of gonorrhea are classed as acute and chronic. Many nen during acute gonorrhea notice a slight burning on urination, perhaps an ease of a vaginal discharge, and discomfort. These symptoms are experienced quently by most women, however, and are usually inconsequential. Other women e had no unusual symptoms and are unaware that anything is wrong until ingitis develops A few women have acute symptoms, comprising definite burning urination, frequency, vaginal pain, itching and leukorrhea.

Chronic gonorrhea of the external genitalia of women, as a rule, does not cause nptoms In a few women, however, the symptoms of chronic gonorrhea of the ernal genitalia never seem to subside. There are leukorrhea and urinary symptoms a continuance of the active and infectious disease. In a few cases cysts of rtholin's glands may cause local inconvenience, recurring abscesses of Bartholin's nds cause local pain, swelling and redness, recurrent burning on urination, and titis Sterility may be the complaint caused by a gonorrheal cervicitis. However, ility does not often occur, for many women who have chronic gonorrhea bear ldren normally

After long periods without symptoms, there may be exacerbation of the infec- n, abscess of Bartholin's glands, cystitis, salpingitis or arthritis.

EXAMINATION. In the acute stage there are general swelling and redness of the ital mucosa accompanied with a purulent discharge from the urethra and cervix. sults of examination of those who have chronic gonorrhea may be negative, or re may be pus expressed from Skene's glands.

DIAGNOSIS. The presence of gonococci in these secretions, demonstrated by smears, by cultures or both, *establishes the diagnosis.* However, in many cases the diagnosis is impossible. The gonococcus is so deeply buried in glands and epithelium that it is inaccessible. Positive results on smears or cultures may be obtained during or near the menstrual periods

a. **Gonorrhea of the Uterine Tubes** (*Salpingitis*). Salpingitis occurring at the time of a menstrual period or after childbirth or miscarriage may be the first manifestation of gonorrhea of the uterine tubes. Many times salpingitis has followed intracervical or intra-uterine instrumentation.

SYMPTOMS During a menstrual period complicated by salpingitis the dysmenorrhea, if present, is increased, the period is *prolonged*, and the flow more profuse After the period the pain continues and increases. Micturition is painful. Leukorrhea, fever, backache, *painful defecation, anorexia, nausea and often vomiting* are not unusual.

In some instances the infection is severe, and if proper antibiotic therapy is not given, recovery may be delayed by *formation of abscess and exacerbations of* symptoms during successive menstrual periods Acute abscesses occur in the uterine tubes or the ovaries (pyosalpinx, ovarian or corpus luteum abscess), in the pelvis (pelvic abscess), Bartholin's glands, urethral glands or perirectal tissues However, if antibiotics are administered, these complications can be minimized or prevented

One attack of acute salpingitis, even without treatment, does not necessarily indicate that more attacks will follow. The patient may recover completely or partially without treatment In the severe infections complete recovery may be assumed when there is restitution of normal childbearing and menstrual functions. The internist is in no hurry to advise surgical operation on a young woman who has acute or subacute salpingitis simply because recovery is slow.

EXAMINATION The abdomen may be moderately distended, and there is bilateral tenderness in the suprapubic region. On occasion the tenderness is limited to the right lower quadrant, requiring a differentiation from acute appendicitis

Muscle guarding is infrequent in salpingitis. Often a mass is demonstrable early in the course of the disease

In many patients who have acute salpingitis a pelvic examination reveals evidence of gonorrhea of the external urogenital tract On bimanual palpation the characteristic findings are bilateral tenderness and increase in the local temperature of the parts. The pelvis is generally and bilaterally sensitive, and movements of the cervix and uterus cause pain. Often no masses are palpable at this stage. There may be only a general sense of resistance and tenderness through the whole pelvis.

There may be found *thickening of the ovarian capsule* and adhesions between the ovary, uterine tube and surrounding organs. Perioophoritis, ovarian abscess, tubo-ovarian cysts, pyosalpinx and tubo-ovarian abscesses are common findings

Thickening of the ovarian capsule and its adhesions causes impediment of ovulation by ovarian adhesions and may result in graafian follicular cysts If so, when the graafian follicle ruptures, virulent gonococci may penetrate the corpus *luteum* and cause a *corpus luteum abscess*

The adnexa may be adherent to the posterior surface of the uterus, and intestines and omentum may become adherent to the fundus, but infection is superficial Intramural abscesses have occurred The endometrium is almost immune to the gonococcus except when traumatized.

Laboratory tests may reveal leukocytosis with an increase in the ratio of the polymorphonuclear cells. The sedimentation rate is increased

DIAGNOSIS. Positive smears and cultures for gonococcus are the only means of establishing a positive diagnosis The history and the findings on examination are usually sufficient for a clinical diagnosis.

Acute salpingitis may closely simulate acute appendicitis, tubal pregnancy and ovarian cyst with twisted pedicle, and it may resemble many other pelvic conditions also. Chronic salpingitis may simulate almost any pelvic disease. With its many pelvic lesions, chronic salpingitis often presents atypical features which may be confusing or impossible of exact diagnosis until biopsy has been made or positive culture for the gonococcus is obtained.

b **Gonorrhea in Pregnant Women.** During pregnancy gonorrhea seems to be able to produce a more serious vaginitis than when pregnancy does not exist. After the uterus has been emptied, during the puerperium, or after the first menstrual period after the puerperium, severe salpingitis often occurs.

c. **Gonococcal Vaginitis in Children.** Gonococcal vaginitis is common wherever persons who are infected with the gonococcus come into contact with girls Gonorrheal infection is conveyed by infected hands, or by infected toilet seats or other bathroom facilities Gonorrheal vaginitis may attain epidemic proportions in orphanages of girl children.

The infection causes a deep inflammation which extends through the epithelial layer into the fibromuscular tunic of the vagina. There is vulvovaginitis, and the labia minora and the inner surface of the labia majora are swollen and red. The chief symptom is a purulent vaginal discharge. There are discomfort, itching, and burning on urination

The course of the disease before the era of antibiotics and chemotherapy was most intractable and persistent. Many patients were not cured until they reached the menarche, when the infection was eliminated physiologically by the natural development of a new type of vaginal epithelium

The diagnosis is established by identification of the gonococcus by smear or culture The presence of a purulent discharge in a girl is suggestive of gonorrhea.

d. **Gonococcal Peritonitis.** An acute gonococcal salpingitis is constantly accompanied by an acute pelvic peritonitis which is limited to the pelvis and disappears spontaneously in a week or 10 days. It produces an acute general peritonitis in children and young girls which is often the first indication of gonorrhea Occasionally an acute peritonitis may arise from a chronic salpingitis General peritonitis secondary to chronic tubal infection may develop as the result of rupture and escape of infectious material from a tubo-ovarian abscess, or pelvic abscess

2 **Pelvic Abscess.** Pelvic abscesses are multilocular, and those intrinsic to internal genitalia of the female communicate with tubo-ovarian abscesses or a pyosalpinx Often they are extrinsic to the pelvic organs and are due to the collection of infected fluid from the rupture or chronic perforation of some intra-abdominal viscus

Pelvic abscesses are enumerated according to the close association and frequency of infection of the structures in and around the pelvis (1) postappendical, (2) salpingitis, (3) postoperative collection of serum or pus, (4) pelvic abscess from perforation of sigmoid or cecum, (5) postoperative hematoma or hematocele; (6) infected hematocele from rupture of ovarian cyst, (7) osteomyelitis; (8) diverticulitis of the pelvic colon, (9) chronic ulcerative colitis or ileitis and (10) puerperal infections

Pelvic abscesses may rupture spontaneously into the bladder, vagina, rectum or sigmoid They may rupture through the abdominal wall, particularly those which arise from chronic ileitis Abscesses from chronic ileitis and from puerperal infection may reach the extraperitoneal fascial planes and burrow around the bladder, between the layers of the broad ligaments, down the fascial planes of the thigh or pass upward into the perirenal fossae. A pelvic abscess may follow the urachus to the umbilicus, and may rupture and drain at that point

Fistulas follow the rupture of the abscess into the vagina, bladder or rectum.

DIAGNOSIS. The presence of gonococci in these secretions, demonstrated by smears, by cultures or both, establishes the diagnosis. However, in many cases the diagnosis is impossible. The gonococcus is so deeply buried in glands and epithelium that it is inaccessible. Positive results on smears or cultures may be obtained during or near the menstrual periods

a. **Gonorrhea of the Uterine Tubes** (*Salpingitis*). Salpingitis occurring at the time of a menstrual period or after childbirth or miscarriage may be the first manifestation of gonorrhea of the uterine tubes. Many times salpingitis has followed intracervical or intra-uterine instrumentation

SYMPTOMS During a menstrual period complicated by salpingitis the dysmenorrhea, if present, is increased, the period is prolonged, and the flow more profuse. After the period the pain continues and increases Micturition is painful Leukorrhea, fever, backache, painful defecation, anorexia, nausea and often vomiting are not unusual.

In some instances the infection is severe, and if proper antibiotic therapy is not given, recovery may be delayed by formation of abscess and exacerbations of symptoms during successive menstrual periods Acute abscesses occur in the uterine tubes or the ovaries (pyosalpinx, ovarian or corpus luteum abscess), in the pelvis (pelvic abscess), Bartholin's glands, urethral glands or perirectal tissues However, if antibiotics are administered, these complications can be minimized or prevented.

One attack of acute salpingitis, even without treatment, does not necessarily indicate that more attacks will follow. The patient may recover completely or partially without treatment. In the severe infections complete recovery may be assumed when there is restitution of normal childbearing and menstrual functions. The internist is in no hurry to advise surgical operation on a young woman who has acute or subacute salpingitis simply because recovery is slow.

EXAMINATION The abdomen may be moderately distended. and there is bilateral tenderness in the suprapubic region. On occasion the tenderness is limited to the right lower quadrant, requiring a differentiation from acute appendicitis.

Muscle guarding is infrequent in salpingitis. Often a mass is demonstrable early in the course of the disease

In many patients who have acute salpingitis a pelvic examination reveals evidence of gonorrhea of the external urogenital tract On bimanual palpation the characteristic findings are bilateral tenderness and increase in the local temperature of the parts. The pelvis is generally and bilaterally sensitive, and movements of the cervix and uterus cause pain. Often no masses are palpable at this stage. There may be only a general sense of resistance and tenderness through the whole pelvis

There may be found thickening of the ovarian capsule and adhesions between the ovary, uterine tube and surrounding organs. Perioophoritis, ovarian abscess, tubo-ovarian cysts, pyosalpinx and tubo-ovarian abscesses are common findings

Thickening of the ovarian capsule and its adhesions causes impediment of ovulation by ovarian adhesions and may result in graafian follicular cysts If so, when the graafian follicle ruptures, virulent gonococci may penetrate the corpus luteum and cause a corpus luteum abscess.

The adnexa may be adherent to the posterior surface of the uterus, and intestines and omentum may become adherent to the fundus, but infection is superficial. Intramural abscesses have occurred. The endometrium is almost immune to the gonococcus except when traumatized

Laboratory tests may reveal leukocytosis with an increase in the ratio of the polymorphonuclear cells The sedimentation rate is increased.

DIAGNOSIS. Positive smears and cultures for gonococcus are the only means of establishing a positive diagnosis The history and the findings on examination are usually sufficient for a clinical diagnosis

tiation of genital tuberculosis from chronic salpingitis is impossible until the tissue studied histologically.

Of the various methods used to establish the definite nature of the adnexitis, rettage is the one most widely used, although exploratory laparotomy, salpingo-aphy, and culdoscopy are also occasionally employed. Curettage is occasionally llowed by exacerbation of the tuberculous process. Inoculation of menstrual blood to guinea pigs can be valuable in establishing the tuberculous nature of salpingitis.

Extra-uterine Pregnancy. The situation of extra-uterine pregnancy most mmonly is the *uterine tube,* rarely the ovary or the abdominal cavity. Ectopic station often occurs with the first pregnancy, if with the second pregnancy, or ccessive pregnancies, a period of sterility may precede the ectopic gestation

When the fertilized ovum is prevented from passing through the uterine tube. tra-uterine pregnancy results Salpingitis is the commonest cause of tubal preg-ancy, but other causes may be present, such as peritubal adhesions or a congenital rrowing Other causes of tubal obstruction are diverticula, rudimentary horn of ouble uterus and pelvic tumors

The sequence of the symptoms may be a preliminary amenorrhea or delayed enstruation followed by irregular bleeding and sudden or repeated pain. There ay have been slight anorexia and nausea, swelling of the breasts and mild pelvic scomfort. Severe pelvic pain, feeling of weakness or faintness, fainting, nausea, omiting, and vaginal bleeding, shock and collapse may develop rapidly In about in every 4 sudden collapse does not occur Patients who do not have sudden ollapse may feel only a sense of profound weakness, faintness, dizziness and capacitation In some instances the patient may suspect that she is having a mis-arriage

As the amount of blood in the pelvis increases and adhesions form, the pelvic iscomfort is increased by an exertion, defecation, and micturition.

On examination the pelvis is so sensitive and the patient in such severe shock at the ruptured tube is not palpable, blood crepitus is usually absent

In the less acute tubal ruptures examination reveals a normal abdomen On elvic examination the cervix is often softened and the uterus is soft and somewhat nlarged The characteristic feature is a soft, sensitive, cylindrical mass in an dnexal region or in the recto-uterine pouch. On rare occasions, if manipulation not considered too dangerous, the ovary on the same side may be isolated, and so, the tentative or presumptive diagnosis of unruptured tubal pregnancy may easonably be made

In tubal pregnancy, as long as the fetus or the trophoblast survives, reaction to e Aschheim-Zondek or a similar test is positive. After the fetal elements die, the eaction becomes negative unless there is a proliferative, independent growth of the ophoblast such as occurs in the presence of hydatidiform mole, or unless there is lso an intra-uterine pregnancy

A specimen of urine is obtained and examined for pregnancy hormones. If re-ults are positive, examination under anesthesia is indicated, and if the findings are onfirmed, laparotomy is performed

In the acute types of tubal rupture the *diagnosis* is established by the history and he acuteness of the onset and collapse. In the less acute type of tubal pregnancy, without acute symptoms, but with repeated attacks of moderate discomfort, the iagnosis is much more difficult The condition may simulate threatened abortion, ppendicitis, salpingitis, ovarian cyst with torsion of the pedicle, ruptured corpus uteum cyst, and a variety of pelvic and abdominal conditions.

Tumors. *Papilloma* of the uterine tube causes no symptoms It is the only com-non benign tumor of the tube Cysts in the broad ligament, remnants of the aroophoron, may be difficult to distinguish from hydrosalpinx.

The fistulas from abscesses of the pelvic organs often heal spontaneously. Fistulas from ruptured diverticula of the colon and those from chronic ileitis never heal spontaneously

In the acute pelvic abscess the symptoms are those of acute salpingitis. The fever is high, the pain intense, and the pulse rapid. In chronic pelvic abscess there may be no acute symptoms The hard mass is found on pelvic examination, made because of vague pelvic complaints

If the patient who has a pelvic abscess suddenly begins to have acute abdominal pain, with nausea and vomiting, there may have been a rupture of the abscess into the abdominal cavity with subsequent *peritonitis. The abscess should be evacuated* surgically.

Abdominal palpation discloses tenderness and perhaps a mass in the lower part of the abdomen Pelvic examination reveals a mass, and there may be fluctuation in the recto-uterine pouch The indurated adnexa may or may not be identifiable. As a rule, in the presence of a pelvic abscess, intrapelvic structures cannot be identified.

Chronic pelvic abscesses are hard and fixed masses, moderately sensitive, and situated behind the broad ligaments.

On rectal palpation the finger is insinuated higher in the pelvis than it can be through the vagina The finger can often determine the extent of the abscess, its relation to the pelvic walls, the cervix and the rectum The presence of pus is indicated by anemia, long-standing illness with the history of fever and infection, and cachexia.

3. ***Genital Tuberculosis in Women.*** The pelvic organs are usually infected with tuberculosis through the blood from distant foci such as lungs, the mediastinal or peribronchial lymph nodes, the intestinal tract, peritoneum or bones The infection occurs usually between the ages of 20 and 40 years In adolescent girls the disease often takes the form of a diffuse, miliary, tuberculous peritonitis with ascites. Aged women occasionally succumb to the disease. Genital tuberculosis is rarely contracted by coitus The uterine tubes are nearly always involved, whereas the ovaries are involved in only about a third of the cases and the uterus (endometrium) in from one half to three fourths of the cases Clinically, tuberculous salpingitis does not differ from other forms of adnexitis Almost always tuberculosis affects both uterine tubes Except for isolated instances of vulval, cervical and vaginal tuberculosis, genital tuberculosis in women means involvement of the tubes

In 1 of every 4 women who have genital tuberculosis there is active pulmonary tuberculosis. Active pulmonary lesions are therefore important symptomatically and diagnostically.

A long history of chronic constitutional and gastrointestinal symptoms accompanied by menorrhagia, dysmenorrhea, amenorrhea, intermenstrual spotting, leukorrhea, sterility, and recurring pelvic and abdominal pain is suggestive of genital tuberculosis. If these symptoms are associated with pulmonary manifestations of tuberculosis they are more significant

If on *examination of a virgin there are found pelvic* lesions indicative of chronic salpingitis, adnexal mass, induration, fixation of the adnexa and unexplained tenderness, a presumptive diagnosis of genital tuberculosis is made

In a married woman, absence of signs of gonorrhea and no reasons to suspect gonorrhea would support the diagnosis of tuberculosis if there was present evidence of a chronic salpingitis.

In the presence of an active pulmonary tuberculosis, a pelvic inflammatory disease may be of tuberculous origin If the cervix is involved, biopsy may reveal the presence of tuberculosis In the absence of active pulmonary lesions the differ-

Small follicular cysts do not cause symptoms. A large cyst or many small cysts in the ovaries may produce pelvic pain, menorrhagia and at times amenorrhea On pelvic examination the ovaries are bilaterally enlarged, tender and cystic. The diagnosis thus is strongly suspected A definite diagnosis may require time and finally histologic studies.

Corpus Luteum Cysts. These cysts may develop rapidly. Once formed, they may remain for a long time.

Pain which is not characteristic and menstrual disturbances are present when there are corpus luteum cysts The menstrual disturbances are the usual ones, menorrhagia, metrorrhagia and amenorrhea. At times these cysts rupture and permit of severe intra-abdominal bleeding, and the symptoms then produced simulate those of abortion or tubal pregnancy Hematomas contained within the cysts, in the presence of salpingitis, may become infected and form abscess (corpus luteum abscess).

Lutein cysts are usually bilateral and multiple, and constitute a mass that may be up to 4 inches (10.2 cm) in diameter. Ovarian cyst is about as accurate a diagnosis as can be made

Cystomas. The ovarian cystomas comprise the simple cystomas, the serous' cystadenomas, and the pseudomucinous cysts. These cysts are histologically benign tumors.

The simple serous cystomas may be unilateral or bilateral. They are unilocular cysts with thin walls and contain clear fluid The serous cystadenomas are filled with a watery fluid The pseudomucinous cystadenomas are multilocular. The contents of these cysts are a thick, glairy, gelatinous material that contains pseudomucin.

The *serous cystadenomas* may occur unilaterally or bilaterally. They attain great size. In the presence of pseudomucinous cyst, fatal results may follow dissemination of pseudomucinous material in the peritoneal cavity during a surgical operation. This condition is known as *pseudomyxoma peritonaei*. There is a rapidly accumulating ascites

On examination the cystomas are found as bilateral, lobulated cystic tumors. On palpation these cysts are not uniform; some portions of the surface are very soft and collapsible, owing to low tension of the enclosed fluid, others are hard and resistant, giving the impression of almost complete solidity, owing to the glandular growth in the wall of the cyst

These different cysts cannot be said to be benign or malignant until seen and examined microscopically.

Tumors Arising from Embryonic Rests of Cells. The tumors of the ovaries which arise from embryonic rests are the granulosa cell tumors, arrhenoblastoma, adrenal tumors of the ovary, dysgerminoma and the Brenner tumor

The *granulosa cell tumor* is a malignant, feminizing, hormone-producing tumor. It causes precocious sexual development in girls and rejuvenation in older women. These tumors may occur at any age but are commonest in childhood They may attain a large size, filling the abdomen Generally they are from 4 to 5 inches (10 2 to 12.7 cm.) in diameter. The most constant feature of the histologic structure is its variability, which can be identified only by an expert pathologist

A precocious sexual development is characteristic The sexual changes are more noticeable before puberty and after the menopause than at intermediate ages In childhood granulosa cell tumors cause precocious development of the reproductive organs, and menstruation begins in a normal fashion but at much too early an age.

After the menopause a granulosa cell tumor causes sexual rejuvenation The breasts become full, the vagina and external genitalia resume the features of mature sexual life The uterus returns to its normal size and menstruation is resumed. It may be irregular or periodically normal. If, therefore, hyperplastic endometrium is obtained on biopsy in the search for the cause of postmenopausal bleeding, a granulosa cell tumor is present if the patient has not received estrogen therapy.

Carcinoma of the uterine tube occurs both primarily and secondarily. Primar carcinoma of the tube is rare; secondary carcinoma is common in abdominal an pelvic carcinomatosis.

Carcinoma is usually situated in the middle or outer third of the tube. The gros appearance of the tumor depends on its size and the situation of and patency of th fimbriated extremity of the tube. If the fimbriated extremity is open, peritonea implantation is the rule, leading to ascites, carcinomatosis and death. Metastasi and dissemination occur early and are widespread

The first symptom of carcinoma of the uterine tube usually is pain. Pain i followed by a vaginal discharge which is bloody. The first symptom may b abdominal enlargement due to ascites and peritoneal carcinomatosis.

The pain may be dull with sharp exacerbations. It may be as severe as the pai in a tubal abortion but without shock because rarely is there any internal hemorrhag in tubal cancer, and hence there are no syncope and shock. Menstrual irregularitie of all types occur, the commonest being metrorrhagia and menorrhagia.

Secondary carcinoma of the uterine tube is commoner than primary carcinoma Being usually metastatic, it generally first starts in the tubal wall as discrete nest and then extends into the tubal lumen.

The diagnosis of carcinoma of the uterine tube is made from histologic studies

THE OVARIES

The ovary lies longitudinally or obliquely against the outer wall of the pelvis. From its upper end proceeds the suspensory or infundibulopelvic ligament and from its lower end the utero-ovarian ligament. The normal graafian follicles and corpus luteum can be palpated on the surface of the ovary in thin women.

Congenital Malformations. Absence of one ovary is rare, but when it occurs, the absence is due to complete agenesis of one urogenital fold, and the corresponding kidney is also absent In the absence of one urogenital fold in the female the uterus is unicornous, derived from only one mullerian duct. The uterine body is fused with the single uterine tube The other uterine tube is likewise absent.

In the ovaries when there is a follicular agenesis, there is no follicular epithelium. The uterine tubes, uterus and breasts are underdeveloped The axillary and pubic hair is absent or scanty and the external genitalia are infantile in type. The urinary gonadotropins are elevated, as they are after menopause The 17-ketosteroids are low. Often there are many other and severe congenital and acquired anomalies. The absence of genital development is often the least of the disabilities present as the result of congenital malformations. In these patients the ovarian failure is a basic lesion in the ovary itself

Tumors. Tumors of the ovaries are often complex structures histologically and may defy the knowledge and ingenuity of the pathologist to classify them. They may be benign or malignant, or they may consist of immature male gonadal elements which secrete male hormonal substances which produce masculine secondary sex characteristics Grossly, on examination by physical means, they are found to be either cystic or solid in structure, benign or malignant in nature. Whether or not they are cystic or solid does not separate them structurally into benign and malignant groups, for both cystic and solid tumors of the ovaries may be found to be malignant.

Retention Cysts. These cysts are benign but may become malignant and originate serous cystomas and cystadenomas. Retention cysts arise from occlusions of germinal epithelium. The germinal layer of epithelium may be present only in the fissures that separate lobulations of the ovary. Cysts are formed when this germinal epithelium is occluded by adhesion

Follicular Cysts. The follicular cysts may originate in normal ovaries or as the result of an inflammatory thickening of the ovarian capsule which prevents rupture of the follicle. Follicular cysts are 1⅕ or 1⅗ inches (3 or 4 cm.) in dia eter and occur bilaterally.

Of the secondary carcinomas of the ovary, the *Krukenberg tumor* (fibrosarcoma ovarii mucocellulare carcinomatodes) involves both ovaries and is usually preceded by or accompanied by a neoplasm in the stomach, intestinal tract or breast. As a rule, there is a history of a previous neoplasm in one of these regions. The original focus of the growth may not have been suspected, however, and it is not discovered until the pelvic tumor is discovered Krukenberg tumors usually occur in women between the ages of 20 and 60 years

Not all secondary ovarian carcinomas have their primary origin in the alimentary tract For instance, carcinoma of the breast may metastasize to the ovary. At least 7 of each 10 of the secondary ovarian tumors are of the same cell type as the original growth.

The symptoms of secondary ovarian carcinoma may be those of the primary growth in the stomach, intestine or breast or may be referred to the pelvis or to an enlarged abdomen On pelvic examination there are bilateral solid ovarian tumors. Often there is ascites Bilaterally enlarged ovarian tumors in a woman who has a tumor of the breast, stomach or intestines are diagnostic The original tumor may have to be sought for after the bilateral ovarian tumors are found The prognosis is generally hopeless

Tumors Arising in the Ovum (Teratomas). Teratomas are embryonic tumors which are characterized by containing one or all of the three primordial layers of tissues ectoderm, mesoderm and entoderm Teratomas are organized to varying degrees into special organs such as hair, teeth, skin, bone, cartilage, thyroid, intestine and other organs.

The younger the ovum is, when the growth disturbance takes place, the more nearly totipotential its cells are and the more capable of producing all their tissues The older the ovum, the more specialized the cells and the less capable they are of producing a variety of tissues and thus the origin of dermoid cysts (MacCallum).

Dermoid cysts are simple forms of teratomas. Teratomas and dermoids may be found anywhere in the body but have a predilection for the ovary

Malignancy is common in teratomas, in dermoids it is relatively rare.

Struma Ovarii. The ovarian tumors which contain thyroid tissue are termed struma ovarii These are in reality ovarian teratomas

Struma ovarii is distinguished by its ability to produce symptoms of hyperthyroidism before removal and occasionally after removal of the thyroid gland. The tumor has a high iodine content This tumor is aberrant endocrine tissue and hence secretes hormones

The chief symptom is an enlarged and uncomfortable lower part of the abdomen At times there may be mild abdominal pain Much of the abdominal enlargement is due to the ascites which is often caused by peritoneal implantations of the tumor. On examination there may be the signs and symptoms of hyperthyroidism accompanied by ovarian enlargement

and myxedema Generally the prognosis is excellent unless the tumor is malignant.

Connective Tissue Tumors of the Ovary. Fibromas and sarcomas are rare tumors of the ovaries They may occur at any age, although sarcomas are found most commonly in younger persons, even in children; fibromas, in adult women These tumors may attain 4 to 6 inches (10 2 to 15.2 cm) or more in diameter. They occur bilaterally, and are often associated with ascites and hydrothorax.

Fibromas differ from sarcomas by remaining within the limits of the ovary There are varieties in appearance and color of fibromas and sarcomas, but the characteristic gross difference in these tumors is that sarcomas are much more vascular than

On palpation the tumor is smooth and may be firm; often it contains cystic portions, but usually it gives the impression of a solid mass.

The diagnosis of a granulosa cell tumor is established by the presence of an ovarian mass, sexual precocity or rejuvenation, and the histologic *presence of cells* suggesting or resembling granulosa cells of primordial follicles of the ovary.

In children the other causes of sexual precocity are cortical adrenal hyperplasia or tumor, pituitary tumors and disorders of the hypothalamus. The removal of a cortical adrenal tumor is followed by disappearance of precocious sexual development. The temporary sexual precocity does not seem to have any *permanent ill* effect.

The *arrhenoblastoma* is a malignant ovarian tumor associated with the defeminization or masculinization of a woman. It is to be differentiated from adrenal cortical hyperplasia or tumor of an adrenal gland. Arrhenoblastoma is always to be considered as a malignant tumor, but as in the malignant granulosa *cell tumor*, recurrence may be very slow in developing

At first there occurs a slow process of defeminization of the woman. Then follows the development of masculine traits such as hypertrichosis, growth of beard, increase in length of clitoris, deepening of the voice, and development of masculine contours.

Adrenal tumors of the ovary are malignant tumors and are said to be histologically like cortical adrenal tissue, resembling the hypernephroma type of cell. The histologic, biologic and clinical resemblance between cortical tumors of the adrenal gland and arrhenoblastomas indicates an embryologic kinship

Cortical adrenal tumors masculinize females and cause sexual precocity in boys In all cases of manifest sexual changes, precocity, sex reversal or rejuvenation, the ovaries, adrenals, pituitary and hypothalamic disorders (see Chapter 14) are studied

The *ovarian dysgerminoma* is usually malignant It does not exert any influence on sexual development or the hormonal balance. It is the homologue of the seminoma, an embryonal carcinoma, a common testicular tumor. The dysgerminoma is supposed to arise in rests of the undifferentiated mesodermal cells of the primitive ovary before these cells develop either male or female characteristics This tumor has a tendency to occur in patients who have sexual maldevelopment such as hypogenitalism and hermaphroditism

Dysgerminomas may be rather large tumors and often bilateral. They are hard, elastic, at times nodular, and may be accompanied with ascites Some of these tumors are malignant, others are possibly benign

The *Brenner tumor* is considered to be a benign tumor It is a rare growth which secretes no hormone When of small size, it appears as a solid mass but when large, it may appear as a cystic adenoma, with large nodular masses on its surface. The Brenner tumor is diagnosable only by histologic study.

Carcinomas of the Ovaries. Ovarian carcinomas occur as both solid and cystic tumors. The solid carcinoma of the ovary develops directly from ovarian tissue. The cystic carcinomas develop from some other ovarian tumor, such as a papillary cystadenoma. Epithelial tumors develop in the dermoids and the teratomas of the ovary.

Solid carcinomas of the ovary begin on the surface of the ovary, involve the whole gland, and extend to involve surrounding structures, the broad ligaments, pelvic floor and peritoneum. They metastasize freely, especially to the lungs. They do not cause any early symptoms. The patients first complain of abdominal enlargement, which is due mainly *to ascites*

On examination carcinoma of the ovary is difficult to palpate, even when fairly well developed In a woman in whom bimanual examination is difficult an insensitive ovarian carcinoma is often impossible to feel

Of the secondary carcinomas of the ovary, the *Krukenberg tumor* (fibrosarcoma ovarii mucocellulare carcinomatodes) involves both ovaries and is usually preceded by or accompanied by a neoplasm in the stomach, intestinal tract or breast As a rule, there is a history of a previous neoplasm in one of these regions. The original focus of the growth may not have been suspected, however, and it is not discovered until the pelvic tumor is discovered Krukenberg tumors usually occur in women between the ages of 20 and 60 years

Not all secondary ovarian carcinomas have their primary origin in the alimentary tract. For instance, carcinoma of the breast may metastasize to the ovary. At least 7 of each 10 of the secondary ovarian tumors are of the same cell type as the original growth.

The symptoms of secondary ovarian carcinoma may be those of the primary growth in the stomach, intestine or breast or may be referred to the pelvis or to an enlarged abdomen. On pelvic examination there are bilateral solid ovarian tumors Often there is ascites Bilaterally enlarged ovarian tumors in a woman who has a tumor of the breast, stomach or intestines are diagnostic. The original tumor may *have to be sought for after the bilateral ovarian tumors are found. The prognosis* is generally hopeless

Tumors Arising in the Ovum (Teratomas). Teratomas are embryonic tumors which are characterized by containing one or all of the three primordial layers of tissues. ectoderm, mesoderm and entoderm. Teratomas are organized to varying degrees into special organs such as hair, teeth, skin, bone, cartilage, thyroid, intestine and other organs

The younger the ovum is, when the growth disturbance takes place, the more nearly totipotential its cells are and the more capable of producing all their tissues. The older the ovum, the more specialized the cells and the less capable they are of producing a variety of tissues and thus the origin of dermoid cysts (MacCallum).

Dermoid cysts are simple forms of teratomas. Teratomas and dermoids may be found anywhere in the body but have a predilection for the ovary.

Malignancy is common in teratomas, in dermoids it is relatively rare.

Struma Ovarii. The ovarian tumors which contain thyroid tissue are termed struma ovarii These are in reality ovarian teratomas

Struma ovarii is distinguished by its ability to produce symptoms of hyperthyroidism before removal and occasionally after removal of the thyroid gland. The tumor has a high iodine content This tumor is aberrant endocrine tissue and hence secretes hormones

The chief symptom is an enlarged and uncomfortable lower part of the abdomen. At times there may be mild abdominal pain Much of the abdominal enlargement is due to the ascites which is often caused by peritoneal implantations of the tumor. On examination there may be the signs and symptoms of hyperthyroidism accompanied by ovarian enlargement

[illegible]

and myxedema Generally the prognosis is excellent unless the tumor is malignant.

Connective Tissue Tumors of the Ovary. Fibromas and sarcomas are rare tumors of the ovaries They may occur at any age, although sarcomas are found most commonly in younger persons, even in children; fibromas, in adult women These tumors may attain 4 to 6 inches (10.2 to 15 2 cm) or more in diameter. They occur bilaterally, and are often associated with ascites and hydrothorax

Fibromas differ from sarcomas by remaining within the limits of the ovary. There are varieties in appearance and color of fibromas and sarcomas, but the characteristic gross difference in these tumors is that sarcomas are much more vascular than

fibromas. In sarcomas secondary growths in the pelvis or throughout the peritoneal cavity, on the intestine and in the omentum, may be present. The pelvis may contain bloody fluid if implantations are present.

Sarcomas are among the most malignant of ovarian tumors. Because they rarely produce any symptoms until they are well developed, cures are rare. Metastasis and direct invasion, with peritoneal implantation, are the common modes of extension.

The diagnosis of both fibromas and sarcomas is made by microscopic study of the tissue The presence of a solid, insensitive, freely movable, hard mass in the region of the ovary suggests a *fibroma*. If ascites is present, the diagnosis is more nearly certain The *diagnosis of sarcoma* of the ovary is more difficult than that of fibroma, because the tumor is softer and may be confused with other ovarian tumors.

Complications of Ovarian Tumor. *Twisting or torsion of the pedicle* of an ovarian tumor is associated more commonly with dermoid cysts, fibromas and cystomas than with other types of tumor If the rotation occurs suddenly, it instantly produces unbearable pain, nausea, vomiting and shock. When the twisting develops slowly, there are often recurring attacks of moderate pain, which may become more severe and constant as the twist becomes tighter

Examination in the case of twisted ovarian pedicle reveals an abdomen that is acutely tender and, in the later stages, rigid. The ovarian mass on pelvic examination usually is palpable The final diagnosis may not be made until laparotomy is performed

Rupture of ovarian cysts is common and occurs in cysts that have thin, distended walls There is usually a history of a fall There may be abdominal discomfort, and often there is severe pain In an occasional instance a cyst may rupture and drain through the vagina without serious consequence.

Free perforation is common in endometrial and corpus luteum cysts. Peritoneal irritation or peritonitis develops if the contents of the cyst are chemically irritating or infected

Intra-abdominal hemorrhage may follow the rupture of an ovarian cyst and produce severe symptoms very similar to those of rupture of ectopic pregnancy. Hemorrhage of varying degrees may occur in connection with ovulation and the rupture of a normal graafian follicle, and this tends to recur with subsequent ovulation

CHILDBIRTH INJURIES

Mechanical Injuries. Mechanical injuries which occur as the result of pregnancy or childbirth commonly involve the reproductive organs, the urinary organs and their supports, and the abdominal wall. Mechanical injuries which involve the supporting structures in the back or the bony pelvis are less frequent.

Mechanical injuries of the reproductive organs and the supporting structures result in lacerations of the perineum in varying degrees (first degree, second degree and third degree), or complete perineal tear, rectocele, enterocele, cystocele, relaxation of vesical sphincter, descensus and retrodisplacement of uterus, prolapse of uterus, cervical laceration and infection, prolapsus of vagina, inversion of uterus, and rectovaginal, vesicovaginal and ureterovaginal fistulas. Some of these injuries, such as relaxation of the vesical sphincter, can be discovered only by special examination (endoscopic examination), although they may produce characteristic symptoms.

Rectocele is a hernia of the rectum into the vagina. It is due to stretching or tearing of the rectovaginal septum. Abdominal and rectal pressure causes the rectum to bulge into the vagina through the weakened rectovaginal septum

Enterocele is located in the recto-uterine pouch and is a hernia through the pelvic floor. It may contain small or large intestine, omentum, or the a

Cystocele is a protrusion or partial hernia of the bladder due to a stretching and relaxation of the vesicovaginal septum. The intra-abdominal pressure and the weight of the bladder and intestine cause the bulging of the bladder into the vagina

Descensus of the uterus can occur only when the broad ligaments and uterosacral ligaments are sufficiently relaxed to allow it. Uterine descensus may be of various degrees of severity; its end stage is prolapse.

Prolapses of the uterus are of three degrees. In *first degree* prolapse the cervix descends to the ischial spines; in a *second degree* prolapse the cervix appears at the vaginal orifice; in a *third degree* prolapse the whole uterus is extruded from the vagina Third degree prolapse and procidentia are synonymous

Prolapse of the vagina occurs in women in whom the vaginal wall lacks adequate support or in whom the supporting structures were so frail that prolapse was inevitable.

Vaginal fistulas are vesicovaginal, ureterovaginal, vesicocervicovaginal, urethrovaginal, or other combinations The commonest type is the vesicovaginal with urinary incontinence. All such fistulas are rare

Injuries to the Cervix. Many parous cervices show unhealed areas round the external os, infection and lacerations which may be only partly healed. The lacerated and infected cervix may be big, boggy and heavy and thus may increase the weight of the pelvic organs. An unhealthy cervix produces annoying vaginal discharges, dysmenorrhea, pelvic pressure, backache and urinary frequency.

Injuries to the Uterus. The commonest endometrial disorder from childbirth is an endometritis as the result of puerperal infection or retained placental tissue. Such an endometritis may become chronic The commonest permanent change in the uterus, however, is chronic subinvolution

Injuries to the Urinary Organs. A discomfort in the pelvis or in either iliac fossa may be due to a urinary lesion, probably in the ureters or the renal pelvis as a consequence of parturition Urologic examinations are required for confirmation of urologic disease to account for the postpartum urinary symptoms.

Injuries to the Abdominal Wall and the Pelvis. The *abdominal wall* is stretched during pregnancy and there may remain diastasis recti and hernia—femoral, inguinal or umbilical—which were created or made worse by gestation

The coccyx is frequently traumatized, a condition which is manifested by local symptoms

The *supporting structures* of the pelvis may be injured by a strain of the ligamentous structures Some of these injuries are the result of the unnatural postures assumed, for instance, the extreme lordosis from marked increase in the abdominal weight

Symptoms of Childbirth Injuries. A sense of pressure in the pelvis and a feeling as though the pelvic organs were protruding into the vagina, while the patient is standing, are common complaints Backache, fatigability, nervousness, irritability, lack of strength and energy, and constipation are not necessarily manifestations of birth injuries of the pelvis

Leukorrhea and urinary frequency are common symptoms of a childbirth injury In cystocele and prolapse there is a partial hernia of the bladder which prevents complete emptying of the bladder by urination and gives rise to subsequent infection and cystitis. Urinary symptoms vary from frequency that accompanies cystocele and prolapse to partial incontinence due to an injury of the vesical sphincter. Partial incontinence manifested by the loss of a few drops of urine on laughing heartily, coughing, sneezing, quickly flexing the body or lifting is a very common complaint.

Complete incontinence is the result of a vesical fistula or destruction of urinary control A constant dribbling of urine, while standing, in a woman who can hold the urine while lying down and can empty the bladder normally when it is filled, often indicates a ureterovaginal fistula.

Anal incontinence may be due to a third degree tear, even though it was repaired at the time, or may be due to a rectovaginal fistula.

Menorrhagia occurs in patients who have chronic subinvolution of the uterus, endometritis, or pelvic congestion following mild degrees of childbed fever. Childbed fever may produce tubal obstruction, endometritis, cervicitis and commonly sterility.

Dysmenorrhea following childbirth injuries is usually a continuation of that which has always been present prior to gestation. In rare instances it may be due to stenosis caused by cervical scar or to uterine misplacement.

STERILITY

CONSTITUTIONAL FACTORS IN MEN AND WOMEN. Constitutional factors which produce sterility include chronic infections, excessive use of drugs, gastrointestinal disorders, lack of physical exercise, obesity, protein or vitamin deficiency, anemia, endocrine diseases, fear, failure to relax, and anxiety or any other conditions that impair the health.

Female Sterility. Sterility is *primary* in the female if she is given adequate opportunity and does not conceive In *relative sterility* the ability to conceive is lessened but not absent. In *one-child sterility* the woman is sterile after bearing one child.

The consensus is that if conception does not occur by the end of one year of married life a couple may be considered unfertile. However, in practice it is far better to wait for at least 2 to 3 years before investigation than it is to begin investigation and treatment with the accompanying nervous tension associated with these procedures

The period of maximal fertility in women is between 18 and 30 years of age Men may retain their fertility much longer than women

The menses need not be regular in order for the ovaries to produce normal ova. If the menstrual periods occur, although in time they may occur irregularly, and if there are present cyclic changes in the cervical mucosa, it generally can be assumed that ovulation is proceeding normally. If there can be demonstrated changes in body temperature during the menstrual cycle, excretion of pregnanediol in the urine, changes in the hormone content of the blood and urine, and cyclic changes in the vaginal mucosa, ovulation is assuredly proceeding normally

Sterility in women is frequently referable to either local or constitutional causes. *Local deformities or disease*, or both, in the genital organs constitute the commonest causes of sterility These local conditions may exist in the vagina, vulva, cervix, uterine body, uterine tubes and ovaries.

The *normal vaginal secretions* are so acid that they kill spermatozoa very quickly. Hence the only spermatozoa that are likely to reach the uterine cavity are those that are deposited on or near the cervix The *cervical secretion* is alkaline and exhibits cyclic changes in amount, cellular content, alkalinity, viscosity and permeability between the ninth and nineteenth days of the cycle

Dyspareunia may be a factor in sterility only when it prevents delivery of the sperm into the vagina It may be due to a variety of lesions imperforate *hymen*, rigid hymen; narrow vaginal orifice following infections, spasm; operative or obstetric scar; absence of vagina or other congenital defect. In the absence of the vagina the urethra may be injured in attempts to use it as a *copulative organ*

Cervicitis rarely causes sterility. Cervical stenosis, polyps or tumors may cause sterility The diagnosis of cervical stenosis is based on finding, by means of the uterine sound, a very small cervical orifice or an unusually narrow cervical canal The stenosis is frequently situated at the internal os.

The *commonest causes of sterility* in the uterine body are hypoplasia, myomas, displacement, endometritis, endometrial hyperplasia, congenital malformation of the uterus, and endometrial polyps.

The significance of disorders of the endocrine glands in fertility varies with the grade and type of derangement. A woman may have a definite endocrine disorder, with delayed menarche, irregular menstruation, and abnormal deposition of fat, without impairing her fertility As a rule, endocrine disorders, if accompanied by uterine hypoplasia, are associated with sterility.

Ovarian failure may be due to congenital defects in ovarian development or may result from fundamental and general endocrine dysfunction The cause of ovarian failure may be a complete agenesis of the follicular epithelium which results in absent ovarian function If the congenital defect is limited to the ovaries, there is lack of development of the breasts, external genitalia, vagina, uterus and uterine tubes and consequently no menstruation. The uterus is very small. The ovaries cannot be felt at all. The diagnosis of follicular agenesis, however, cannot be made without histologic examination of the ovaries. Agenesis of the follicular elements is not always complete. Menstruation may occur a few times each year. Pregnancy is not likely to take place in such women.

A common cause of sterility is *obstruction of the uterine tubes.* The common cause of obstruction is salpingitis, which may be gonococcal, tuberculous or puerperal. Other effective agents for closing the uterine tubes are uterine retrodisplacement, uterine myomas, ovarian cysts, parovarian cysts and congenital occlusion of the tube

Tubal insufflation with air provides one means of determining the patency of the uterine tubes The injection of radiopaque fluid into the uterine cavity and forcing of this fluid into the uterine tubes (hysterosalpingography) is another method for determining patency of the tubes Both of these methods have their protagonists.

The contraindications to either test are acute or subacute infections of the genital organs, uterine bleeding (menstrual or abnormal), and recent curettage, abortion or intra-uterine operation

The passage of gas through the tubes is manifested by the whistling sound heard over each iliac fossa by means of the stethoscope; by the presence of shoulder pains after sitting up; and by the shadow of the subphrenic bubble of gas on the roentgenogram, taken with the patient sitting up.

In using hysterosalpingography, a radiopaque fluid is injected through the cervix, when the tubes are patent, the fluid flows into the uterine cavity, through the uterine tubes, and escapes into the pelvic cavity.

Hysterosalpingography has not been universally accepted.

Male Sterility. It is said that from 10 to 15 per cent of marriages are barren and that the male is either a contributory or sole cause in from 30 to 60 per cent of these barren marriages.

Certain inflammatory lesions cause sterility by destruction of the germinal epithelium of the testis, as may occur in orchitis of mumps. Other inflammatory conditions, such as gonorrhea or nonspecific infections, cause sterility by occlusion of the seminal ducts Abnormal development of the testes, as in cryptorchids, often results in sterility, as do congenital abnormalities of the accessory sex organs: the epididymides, vasa deferentia and seminal vesicles. A less well-understood and considerably commoner condition is impaired male fertility which results in imperfect spermatogenesis or hypospermatogenesis Hypogenitalism, hypospadias, scars, and stenosis of the external urethral meatus may be cause for imperfect or no spermatogenesis

The relation of infections in the *prostate and seminal vesicles* to impaired male fertility is questionable.

Stricture of the urethra may hinder normal ejaculation.

At ejaculation the *semen is an opalescent fluid* consisting of spermatozoa mixed with the secretions of the epididymides, vasa deferentia, seminal vesicles, prostate gland and urethral glands. The average volume is given as 3 5 ml. Figures for normal

Anal incontinence *may* be due to a third degree tear, even though it was repaire at the time, or may be due to a rectovaginal fistula.

Menorrhagia occurs in patients who have chronic *subinvolution* of the uteru endometritis, or pelvic congestion following mild degrees of childbed fever Childbe fever may produce tubal obstruction, endometritis, cervicitis and commonly sterilit

Dysmenorrhea following childbirth injuries is usually a continuation of th which has always been present prior to gestation. In rare instances it may be due stenosis caused by cervical scar or to uterine misplacement

STERILITY

CONSTITUTIONAL FACTORS IN MEN AND WOMEN Constitutional factors whi produce sterility include chronic infections, excessive use of drugs, gastrointesti disorders, lack of physical exercise, obesity, protein or vitamin deficiency, anem endocrine diseases, fear, failure to relax, and anxiety or any other conditions t impair the health

The *normal vaginal secretions* are so acid that they kill spermatozoa very quickly. Hence the only spermatozoa that are likely to reach the uterine cavity are those that are deposited on or near the cervix. The *cervical secretion* is alkaline and exhibits cyclic changes in amount, cellular content, alkalinity, viscosity and permeability between the ninth and nineteenth days of the cycle

Dyspareunia may be a factor in sterility only when it prevents delivery of the sperm into the vagina It may be due to a variety of lesions imperforate hymen; rigid hymen, narrow vaginal orifice following infections, spasm; operative or obstetric scar, absence of vagina or other congenital defect. In the absence of the vagina the urethra may be injured in attempts to use it as a copulative organ

Cervicitis rarely causes sterility. Cervical stenosis, polyps or tumors may cause sterility. The diagnosis of cervical stenosis is based on finding, by means of the uterine sound, a very small cervical orifice or an unusually narrow cervical canal The stenosis is frequently situated at the internal os.

The commonest causes of sterility in the uterine body are hypoplasia, myomas, displacement, endometritis, endometrial hyperplasia, congenital malformation of the uterus, and endometrial polyps.

The significance of disorders of the endocrine glands in fertility varies with the grade and type of derangement. A woman may have a definite endocrine disorder, with delayed menarche, irregular menstruation, and abnormal deposition of fat, without impairing her fertility. As a rule, endocrine disorders, if accompanied by uterine hypoplasia, are associated with sterility.

Ovarian failure may be due to congenital defects in ovarian development or may result from fundamental and general endocrine dysfunction The cause of ovarian failure may be a complete agenesis of the follicular epithelium which results in absent ovarian function. If the congenital defect is limited to the ovaries, there is lack of development of the breasts, external genitalia, vagina, uterus and uterine tubes and consequently no menstruation. The uterus is very small. The ovaries cannot be felt at all The diagnosis of follicular agenesis, however, cannot be made without histologic examination of the ovaries. Agenesis of the follicular elements is not always complete. Menstruation may occur a few times each year. Pregnancy is not likely to take place in such women

A common cause of sterility is *obstruction of the uterine tubes.* The common cause of obstruction is salpingitis, which may be gonococcal, tuberculous or puerperal Other effective agents for closing the uterine tubes are uterine retrodisplacement, uterine myomas, ovarian cysts, parovarian cysts and congenital occlusion of the tube.

Tubal insufflation with air provides one means of determining the patency of the uterine tubes. The injection of radiopaque fluid into the uterine cavity and forcing of this fluid into the uterine tubes (hysterosalpingography) is another method for determining patency of the tubes. Both of these methods have their protagonists

The contraindications to either test are acute or subacute infections of the genital organs, uterine bleeding (menstrual or abnormal), and recent curettage, abortion or intra-uterine operation

The passage of gas through the tubes is manifested by the whistling sound heard over each iliac fossa by means of the stethoscope, by the presence of shoulder pains after sitting up, and by the shadow of the subphrenic bubble of gas on the roentgenogram, taken with the patient sitting up.

In using hysterosalpingography, a radiopaque fluid is injected through the cervix; when the tubes are patent, the fluid flows into the uterine cavity, through the uterine tubes, and escapes into the pelvic cavity

Hysterosalpingography has not been universally accepted

Male Sterility. It is said that from 10 to 15 per cent of marriages are barren and that the male is either a contributory or sole cause in from 30 to 60 per cent of these barren marriages.

Certain inflammatory lesions cause sterility by destruction of the germinal epithelium of the testis, as may occur in orchitis of mumps. Other inflammatory conditions, such as gonorrhea or nonspecific infections, cause sterility by occlusion of the seminal ducts Abnormal development of the testes, as in cryptorchids, often results in sterility, as do congenital abnormalities of the accessory sex organs: the epididymides, vasa deferentia and seminal vesicles A less well-understood and considerably commoner condition is impaired male fertility which results in imperfect spermatogenesis or hypospermatogenesis Hypogenitalism, hypospadias, scars, and stenosis of the external urethral meatus may be cause for imperfect or no spermatogenesis.

The relation of infections in the *prostate and seminal vesicles* to impaired male fertility is questionable

Stricture of the urethra may hinder normal ejaculation

At ejaculation the *semen is an opalescent fluid* consisting of spermatozoa mixed with the secretions of the epididymides, vasa deferentia, seminal vesicles, prostate gland and urethral glands The average volume is given as 3.5 ml Figures for normal

volume, however, vary considerably and volumes from less than 2 ml. to more than 7 ml. may be normal. Very small amounts of semen may mean occlusion of the spermatic ducts.

Normally the *semen is thick and viscid* when ejaculated. It should liquefy readily, however, and be fluid *within less than half an hour. At least one half of the spermatozoa should be actively motile* after 2 to 10 hours.

Brown has made some investigations of male seminal fluid with a view to determining whether or not modification in the character of this fluid or increase in its amount might serve to protect the spermatozoa over a longer period of time and make more likely the contact of the sperm cell with the ovum. Man normally produces about 120,000,000 spermatozoa for each milliliter of fluid, or approximately 450,000,000 in the average ejaculate. A donor may produce a total of 30,000,000 to 50,000,000 spermatozoa every 24 hours daily over a considerable period. When it is realized that only one spermatozoon can impregnate the ovum, the tremendous factor of safety involved becomes apparent These studies lead to the conclusion that such influence as the glandular secretions of the male have on the spermatozoa cannot be further increased by the addition of fluid to the normal ejaculate

If more than 1 in every 5 spermatozoa are found to be abnormal, it is evidence of impaired fertility

A *decrease in the normal number of spermatozoa* is one of the commonest causes of low fertility. Spermatozoa counts of less than 60,000,000 per milliliter are inadequate.

Absence of spermatozoa in the semen results either from failure to produce sperm (aspermia) or from mechanical blockage of the seminal ducts. Congenital abnormalities of these structures are hypospadias, absence of the vasa deferentia, epididymides, seminal vesicles or ejaculatory ducts, imperfect union of testis and epididymis and congenital stricture of the vas deferens

Lack of spermatogenesis may be due to the various types of pituitary disease or to destruction of the germinal epithelium of the testis from inflammatory lesions such as orchitis of mumps, or tuberculosis, or to failure of normal testicular development as in cryptorchids

Functional Impotence. Functional impotence of the male may be due to in-[illegible] because of fear of the sexual act, fear of having children,
[illegible] the sexual act normally. Worry

It is well for the diagnostician to remember that many men and women who, after various tests and examinations, have been declared sterile, nevertheless have enjoyed rearing their own families despite the grave predictions to the contrary.

DERANGEMENTS OF SEX LIFE

The consultation is a solemn moment to the patient, man or woman. Under its influence patients find themselves confessing to the physician and asking for help which might well be sought from a minister of the gospel. When a patient is in this [illegible] can well listen and by *listening he is practicing* sound morality
[illegible] physician's affair to mend the patient's
[illegible]gularities as to encourage him to stop drinking himself to death Sexual irregularities are never normal sexual behavior.

Description of what should be considered a normal sex life can only lead to hopeless disagreement not only with one's peers but even with one's self. *It is not* the prerogative of the physician to outline the normal sex life to men and women, for the sex impulse is a normal appetite, as variable as any that can be imagined The physician is never afraid to hold up to his patients the frank ideals of a cleaner life than it would seem possible *for some of them to aspire to.* The strictest morality that can be imagined must always be outlined as routine behavior. In time delight

will come to those who give such advice; for often a responsive glow, a determination to be better, will be aroused in the most unpromising material

Morally upright and profoundly religious mothers may have read certain books about The Things Women Should Know About Their Sex Life If such a woman has not experienced an orgasm, she may inquire of the physician the reason for her lack of such an experience.

In answer to such a query it should be briefly but clearly stated that in women orgasm is a nervous reaction based on the presence of healthy reproductive organs and psychic response. It is dependent too on normal pituitary and ovarian function. If desire and orgasm have been developed without frustration, they continue irrespective of the presence of the ovaries or uterus. Even though these reactions have not been attained, if normal genital organs are present, reproduction may be possible, for there are many women who have never experienced an orgasm who have large families. It is therefore clear that while the orgasm is desirable, it is not necessary for breeding in women For the physician to enter into a psychiatric cross-examination of such a woman is nothing short of bestial brutality for such questioning is sure to offend her finer sensibilities

The removal of the ovaries shortens the span of sex life by altering the physical character of the external genitalia and the vagina. Women become indifferent sexually and have less orgasm after menopause

SEXUAL OFFENCES

The physician is consulted in regard to two types of sexual offence The first is a mental disturbance of which the crime is only a manifestation These crimes consist of repeated indecent exposure, indecent assaults upon children, lewd and libidinous practices, and the criminal acts of sadism and masochism.

The second group are deliberate sexual crimes by persons in a sane though perhaps morally degraded frame of mind Rape, incest, and sodomy and bestiality are the common offences

Rape. Rape is unlawful carnal knowledge of a woman without her consent "Unlawful" implies that there is such an act as a lawful carnal knowledge of a woman by force "Carnal knowledge" is "the slightest degree of penetration of the vulva by the penis" Penetration proper through the hymen is not necessary to the act. When the hymen is already deflorate, ruptured by previous penetrations, a great deal depends on the girl's character and bearing, the substance of her story, the condition of her clothing, and the presence of even trivial injury to any part of the body.

Evidence of a forceful assault freshly committed will be clear. There will be bruising, scratching, or tearing of the vulva or hymen which may still be bleeding

It is possible that the only proof of penetration will be a vaginal smear of seminal fluid For this reason a swab or smears should always be taken The emission of seminal fluid is not essential to the proof of carnal knowledge but its demonstration may provide proof of penetration.

The development of gonorrhea or of pregnancy in a woman after alleged rape may sometimes be used as corroborative evidence without giving it undue value, and culture as well as microscopic examination of a swab should be made if possible.

The essence of the offence is that it should take place against the desire of the woman In females less than 18 years of age the offence is carnal abuse with or without consent The age limit of 18 years may vary in accordance with local statutory law

Medical Examination in Alleged Rape. The precise time of the examination and a record of by whom it was requested are essential to record.

The raped girl or woman is shy and bewildered The story, in the girl's own words, is recorded at the time, for it will contain conversation the exact form of which may be vital. No false modesty in detail or language should be allowed to interfere with this being a full record It will gain by being graphic and tend to appear in its true light—authentic or false.

The presence of tangled, disordered hair, dirt-stained face or hands, and the condition of the clothing, tears and blood stains are recorded.

With some person present to assist, the clothing should be removed in the doctor's presence, and examination made of every part of the body. Stories of being forced against something, pinned down, gripped by the arms, kicked or punched may gain corroboration from the finding of some comparable injury in the part described

The local parts are examined for foreign hairs, to be placed in envelopes, sealed and labeled Seminal stains are smeared on slides and fixed Bruises, scratches or tears adjacent to the vulva and within it, as well as to the neighborhood of the hymen, are searched for. The state of the hymen is observed and recorded

Matted, semen-stained pubic hairs may be cut away. Dried thigh stains should be moistened with saline solution and smeared on glass slides. A vaginal swab should always be taken If the material is still wet, the peculiar odor of semen competently observed is fairly conclusive.

It is less common for the doctor to have the opportunity of examining the man accused of rape: permission must be obtained and its voluntary nature made clear before commencing The physician searches for foreign hairs on the clothing, adherent to the body or pinned under the prepuce Injury to the penis is rare, but scratches to the face or hands occur frequently (Keith Simpson).

DISEASES OF THE SKIN, SUBCUTANEOUS TISSUES AND BREASTS

The skin is a protective, respiratory, excretory, heat-regulatory, absorptive, vitamin-producing and immunity-producing organ Its prickle cell layer contains the sense organs for tactile, pain, heat and cold sensations.

Layers of the Skin. The skin is composed of two main layers or parts: (1) the epidermis or cuticle and (2) the true skin. The *epidermis* or cuticle (scarf skin) is composed of the following layers beginning from the outside, the horny layer (stratum corneum); the transparent layer (stratum lucidum), the layer of flattened granular cells (stratum granulosum), the mucous layer (stratum mucosum) which contains pigment and prickle cells (prickle cell layer); the basal cell layer (stratum germinativum). The *true skin* consists of an outer or papillary layer, which contains the nerve endings and capillaries, and a deeper layer, which is largely composed of fibrous bundles. Beneath the skin is the subcutaneous connective tissue

The expanse of skin over the body is designated by topographic regions, for instance, skin of the scalp and skin of the leg These are topographic regions which normally grow hair. The regions which do not grow the regular coarse hair are designated as glabrous skin

Pigmentation of the Skin, Eyes and Hair. The stratum mucosum of the epidermis, as has been stated, contains the pigment or coloring substance, the melanin The melanin is composed of small granules which are deposited in the deep layers of the epidermis and iris and disseminated through the cells of the shafts of the hair The mucous membranes, sclerotics and some other tissues of the body contain this substance. The pigmentation of an individual is subject to change throughout different periods of life Other changes are brought about by age and exposure to sunlight and to confinement The state of feeling of the individual and the presence or absence of an oily coating of the skin likewise influence its color. In the hair the presence of air bubbles between the hair cells and the loss of melanin cause grayness of the hair, normally with aging and, allegedly, suddenly after great emotional strain.

The function of the pigmentation is to protect the individual against sunlight. The absence of pigment results in albinism with its accompanying sensitive white skin and reddened eyes which are extremely sensitive to light

Racial Colorations. Early man was a product of the tropics and subtropical regions He had brown skin, hazel to dark brown eyes and reddish brown to black [illegible]

Because of the climatic influences of the post-Glacial period the original skin pigment began to be lost, and as a result of these environmental influences and mut[illegible]
the [illegible]
to a [illegible]
in northern Europe, and thus the Celto-Slavic or Alpine coloration came into existence; while in southern Europe depigmentation was still less, leaving much of the original skin coloration and resulting in the Mediterranean complexion of swarthy

brown, with dark eyes and black hair. The continuous residence of those remaining in the tropical countries seems to have increased their skin coloration and thus resulted in the black-skinned individuals (Negroes). The Nordic white skin, the blue eyes and the blond hair still contain some of the ancient pigment. The eyes are blue because this old brown pigment is limited to the posterior cells of the iris, and the blue coloration results from refraction, whereas when the iris is viewed from behind, it is brown or dark

Freckles (*Ephelis, Lentigo*). The familiar freckles of the skin occur in those who have red hair or a tendency thereto; also in individuals who have white skins or in admixtures of white-skinned and black-skinned individuals.

A freckle is a pigmented spot, brownish in color, on the skin It is due to discrete accumulation of pigment in the rete. Freckles vary in size, in color and in number on different individuals They are made prominent by exposure to sunlight and wind. The term cold freckles is applied to those occurring on a part of the body under the clothing which is not exposed directly to the sun The origin of these freckles is the same as of those caused by direct exposure to the sun. They are less densely pigmented spots

Freckled skins are proved to be susceptible to senile keratosis and skin cancer in aging individuals.

Leukoderma. Leukoderma occurs at all ages, but among white peoples it is more common in the middle-aged than in the young. The eruption commences as a small white patch, which may enlarge and spread The disease is more frequent and extensive in hot climates and during the summer months than in other climates and seasons The lesions often occur on the face, hands, scalp and trunk, and may be symmetrically distributed The individual patches do not reveal thickening of the skin, and when they are examined for the sense of touch and pain, anesthesia is not present. When the scalp is involved, the hair on the patches turns white

The normal skin sensitivity is of importance in the differential diagnosis between leukoderma and leprosy Scleroderma may show some whitening of the areas involved, but has a distinct boardy hardness Some observers incline to the view that leukoderma is of nervous origin Actinic rays in many cases have an influence in determining its origin and localization Differentiation of leukoderma from the fully developed lesion of pinta is difficult In pinta, however, there will be other lesions of varying colors which have not yet become white (For more about pinta, see Chapter 17)

Chloasma. Chloasma is a disease the opposite of leukoderma There is a spotted increase in the normal color of the skin In chloasma the increased pigmentation has an internal origin Chloasma (or chloasma-like spots) is associated with pregnancy. There are many cases of uncertain origin Chloasma is erroneously attributed to hepatic disease (liver spots)

Acanthosis Nigricans. Acanthosis nigricans is a rare disease affecting the flexures and often resembling ichthyosis. The brown and, at times, the almost black, velvety linear overgrowth in the region of the flexures is characteristic The mucous membranes often are affected, showing warty growths without pigmentation This condition frequently is associated with widespread internal malignant disease. Besides resembling ichthyosis, acanthosis nigricans resembles Darier's disease.

Transient Coloration, Texture and Moisture. No decision concerning the color of the skin should be made until the mucous membranes of the mouth and conjunctivae have been observed Exposure to wind and weather dries, hardens and darkens the skin as well as producing other effects of less obvious magnitude. *Habitual pallor* is seen in persons who live an indoor life or who sleep in the daytime. A transient pallor of the skin may be the result of weakness of the heart action, as is observed in syncope, chills, nausea and arterial spasm. Sudden pallor, which is constant for the time being, is present when large and rapid hemorrhages

occur and when the heart fails abruptly. A slowly developing pallor is usually the result of anemia. The pallors are often described in terms of varying tints In diagnosis, however, such descriptions are worthless.

An unusual redness of the skin depends on hyperemia, the overfilling of the cutaneous capillaries with blood. Hyperemia of the skin follows a warm bath, friction of the surface of the skin, or exercise Long exposure to heat and cold and moisture produces a purplish redness of the skin of the hands which is not significant of systemic disease. *Diffuse redness* of the skin is seen in fevers, after the administration of certain drugs, and after the ingestion of alcoholic beverages. Localized redness of the skin, such as the redness of one cheek in acute lobar pneumonia and the unilateral redness of the face which attends histamine cephalalgia (Horton's headache), are observable phenomena In some *chronic alcoholics* the face is a dusky red Not all persons who have dusky red faces, however, are chronic alcoholics. The so-called dusky red face is the result of cyanosis of the skin, which is characterized by a blue or purplish tint This color arises from imperfectly oxygenated blood in the capillaries *Cyanosis* is best observed in the lips and mucous membranes and in the fingernails, if nail polish has not been used, because of the thinness and translucency of these epithelial coverings Cyanosis of the skin is caused by any condition which hinders the admission of air to the lungs, lessening the working, breathing surface of the lungs, and by any condition which interferes with pulmonary or systemic circulation Stated in more precise terms, cyanosis is due to improper oxygenation of the erythrocytes The *texture of the skin* is soft and elastic, and the skin is moist to the touch

Hyperhidrosis and Anhidrosis Excessive moisture or sweating of the skin is *hyperhidrosis,* and dryness of the skin is *anhidrosis* (see Autonomic Nervous System, Chapter 23).

Sweating of the hands or the feet attends general debility, hyperthyroidism and Raynaud's disease. It is most commonly due to nervousness. Unilateral or one-sided sweating of the head and face may be present in histamine cephalalgia (Horton's headache), neuralgia and other affections of the nervous system. Unilateral or bilateral sweating of the face may occur during a meal

Anhidrosis is characteristic of all febrile diseases, especially if the temperature is high and the rise is prolonged If the skin is injured by stretching, which alters its structure so that the cutaneous circulation is hindered, as in general anasarca, lymphedema or myxedema, anhidrosis exists as a direct result. Anhidrosis accompanies diseases in which there is an excessive loss of fluids for any reason. When renal functional activity is severely impaired, the sweat may have a urinous odor and may deposit white scales or crystals of urinary solids on the skin

Colored Sweat Yellow sweat from the biliary pigment may occasionally be present in severe jaundice. Blue, brown, yellow or red sweat has been observed in hysteria The condition characterized by colored sweat is known as *chromhidrosis.* Very rarely, bloody sweat, *hematidrosis,* is caused by capillary hemorrhage into the sudoriparous glands This condition may follow the administration of dicumarol

Dermographia. Dermographia is a condition in which tracings made on the skin leave a distinct reddish elevated mark *Dermographia alba* is the white line formed on the skin in the epinephrine test *Black dermographia* is the dark streak produced under certain conditions by stroking the skin with certain metals.

According to Urbach and Pillsbury, the black writing which appears on the skin following application of certain blunt metallic implements with moderate pressure represents not a chemical but a physical process due to the particles of the metal rubbed off by friction and remaining on the skin. While it was originally assumed that a hysterical condition was a necessary prerequisite for the phenomenon, Emdin later retracted this idea

Black dermographia is frequently observed in women who wear trinkets and

cheap jewelry of silver and gold on powdered areas. The same effect occurs on skin surfaces soiled with street, factory or mine dust.

In principle the phenomenon may be evoked on any human skin by the use of appropriate inorganic powders. There are individual differences due to variations in the moistness and oiliness of the skin. The phenomenon will appear in all persons who have dry, nonoily epidermis. The fact that the phenomenon can be evoked in the skin of a corpse conclusively demonstrates that this process cannot be regarded as a biologic reaction

History. When a disorder of the skin is present it is well to learn: (1) the duration of the disease, (2) whether there have been previous similar attacks of the eruption, (3) whether the onset of the disease was accompanied by fever, malaise, headache or generalized pains, or has been accompanied by disturbances of digestion or of the urogenital or nervous systems, and (4) whether there have been any enlarged lymph nodes

Examination. The examination of the skin should always be conducted in daylight if at all possible Of basic importance in diagnosis are detailed examination of the lesion or lesions, especially of the primary lesion, and palpation of the eruption Primary skin lesions are known as macules, papules, vesicles, pustules, wheals and hives. The secondary skin lesions are described as scales, crusts, scabs, excoriations, fissures, ulcers and scars These primary and secondary lesions may be acute or chronic. The primary lesions are of the greatest importance in diagnosis A magnifying glass used to distinguish the character of the lesion may be of great aid. The examination is performed in a definite order, beginning with the head, mouth, neck, and proceeding to the thorax, upper extremities, lower extremities and, finally, the soles of the feet and the palms of the hands It is during the examination that the examiner often is able to obtain a precise history as to whether the eruption began universally, or was widely scattered, or was grouped on the flexor or extensor surfaces of the body During the time of the examination the patient usually will mention whether the lesions began by itching, burning, hyperesthesia, anesthesia, or with pain

There are predispositions to many diseases of the skin. During childhood the common predisposing causes of skin disease are, first, those of hereditary origin, for instance, the congenital nevi and nevoid diseases, which include such disorders as ichthyosis and keratosis palmaris. Congenital syphilis may not become manifest until adolescence In later life there is a tendency toward seborrheic eczema, presenile alopecia and pigmentary disorders of the skin

Infants are subject to various infantile dermatoses and to napkin eruptions. Acne, seborrhea and hyperhidrosis occur in adolescence, whereas in advanced age epithelioma, keratosis and general pruritus develop. The relation of sex to skin disease is often important Carbuncles occur twice as often in men as in women Women are more subject than men to lupus erythematosus. Leukomelanoderma of syphilis is practically limited to women. Women suffer from contact dermatitis from the use of cosmetics, whereas men suffer more from occupational dermatitis and leukoplakia of the mouth During the winter months such diseases as psoriasis, seborrheic dermatitis, ichthyosis and chronic eczema are worse than in summer Scabies and contact dermatitis due to soap, wool and furs are commoner during the winter than in summer. During the summer months, diseases of the skin as the result of contact with various poisonous plants, hyperhidrosis, urticaria, dermatomycoses and miliaria are commoner than during the winter. In summer the insects that sting or bite and the animal parasites that suck blood are prevalent.

DISEASES OF THE SKIN

DISEASES DUE TO PRENATAL INFLUENCES

Ichthyosis. Ichthyosis is both familial and congenital. It has been thought to be due to a persistence of a fetal layer of skin, the epitrichium.

In cases of ichthyosis the secreting glands of the skin are absent. Perspiration is impossible, and the patient suffers in hot weather from vascular congestion and the lack of oil. In cold weather the extremities are susceptible to chilblains The skin is easily irritated, is hard, horny in appearance with marked dryness, harshness and formation of heavy scales. Only the flexures escape involvement. The hard masses of scales often crack across and in so doing produce fissures which become infected with pyogenic organisms.

The mildest phase of ichthyosis is termed xeroderma. All gradations between xeroderma and typical ichthyosis are observed. In the completely developed ichthyosis large platelike scales are present all over the body, but generally are worst on the extremities.

Keratosis Palmaris et Plantaris. This is a hereditary and congenital disease of the skin which affects the palms and soles and often is manifest at an early age. The lesions in appearance are like keratotic lesions on senile skin

Lichen Pilaris (Keratosis Pilaris) Around the hair follicles along the anterior surfaces of the thighs and over the outer surfaces of the arms are often observed small, firm papules that are not inflammatory These papules are discrete and at times may itch They are arranged in patches and are ill defined, and frequently some of them are capped with crusts of dried blood as the result of scratching Keratosis pilaris usually does not produce symptoms

Epidermolysis Bullosa. This is often a hereditary condition which begins in infancy and is manifested by bullae which appear after the slightest trauma. In the development of the lesions there is first redness, then wheals, and the bullae appear in less than one-half hour The patient's skin is more elastic than normal. Often there is dystrophy of the nails Epidermal cysts are of common occurrence.

Adenoma Sebaceum. This is a rare condition which even more rarely occurs alone. It is often associated with congenital nevi, fibromas, warts, rhabdomyoma and convulsive disorders and defective minds

The lesions are manifested soon after birth as small flattened tumors of the sebaceous glands on the face In the beginning the yellowish, individual lesions are small, 1 or 2 mm in diameter. Around these yellowish areas there often are dilated capillaries

Keratosis Follicularis (Darier's Disease). Morbid heredity is the only known cause of Darier's disease, which runs in families and commences in youth. There are no lesions of the mucous membrane The disorder is not associated with malignant disease Although the disease normally is chronic and slowly progressive, acute exacerbations may occur with the rapid production of fresh patches, but the general health of the patient is not impaired

This disorder is characterized by crusted dark brown papules, often coalescing in symmetric areas on the face, scalp, trunk, flexor aspects of the limbs, axillae and genital regions When the crusts are removed from the papules, there are discernible on the undersurface of the crusts horny plugs corresponding to dilated follicular openings Removal of the crusts causes bleeding Sebaceous material can be squeezed out of the follicles after the crusts are removed

Monilethrix. Monilethrix is a congenital and familial dystrophic condition in which the hair shows regular nodal constrictions at which it is likely to break off. Associated with the dystrophy is keratosis pilaris, a hyperkeratosis of the follicular stomas The hair is thinly distributed in the beginning After many hairs have broken off, the remaining hairs are set beside the short ones; both long and short hairs display variations in thickness and impart a shabby appearance to the scalp

Hereditary Xanthomatosis. Bloom and his co-workers recorded hereditary xanthomatosis as it occurred in 9 children of Syrian descent whose parents were second cousins The parents of these tainted siblings had no cutaneous or cardiovascular symptoms, although the father had hypercholesteremia. The mother had

8 half siblings, and 5 of them also had hypercholesteremia. This appears to support the hypothesis that hypercholesteremia rather than xanthoma tuberosum is the principal directly inherited factor and that this disturbance of lipid metabolism under certain conditions leads to cutaneous and cardiovascular changes. The hereditary cause of the disorder has been demonstrated but no adequate statistical data are available that warrant a final analysis of the genetic mechanism involved (see Lipidosis, Chapter 22).

Xanthomas are small, flat plaques of a yellow color in the skin. Microscopically the lesions reveal light cells with foamy protoplasm

Tuberous Sclerosis. Tuberous sclerosis is a rare heredofamilial disease in which there are multiple neurospongioblastomas in the brain The nodules and the accompanying sebaceous nodules of the skin have a moderately firm consistency, which is fancied to be that of a potato, hence the name tuberous Tumors often coexist in other organs, notably hypernephroma of the kidney and rhabdomyoma of the heart. The child is usually epileptic and mentally deficient.

The presence of sebaceous adenomas, small, closely set papular tumors of the skin, pink or brownish, appearing symmetrically on the face, chiefly about the nasolabial folds, bridge of the nose, forehead and chin, is the chief diagnostic feature The nodules sometimes are on the skin of the trunk and the intergluteal fold These cutaneous growths appear in adolescence, and therefore the condition may be difficult to recognize prior to this age The tubers may be situated within the cranial cavity and originate the localized or generalized symptoms of brain tumor

BACTERIAL INFECTIONS OF THE SKIN

Infections by the staphylococcus are the most common infections of the skin The staphylococcus produces furuncles, impetigo contagiosa, pyoderma, sycosis vulgaris and pyogenic paronychia The streptococcus too is a common cause of skin infections. It causes more serious infections of the skin than the staphylococcus, such as ecthyma, erysipelas and scarlet fever

Staphylococcal and Streptococcal Infections. *Acute staphylococcal dermatosis* is characterized by pustular follicular lesions. The appearance of the lesions varies with their depth The commonest form of the dermatosis is a superficial infection of the openings of the hair follicles These lesions are common and give little or no discomfort. Usually they are brushed away by bathing or by the clothing without one's knowing of their presence. Deeper infections of the follicles result in boils or furuncles

Furunculosis is more frequent in hot weather than at other times and may result from the rubbing of clothing, such as a collar, suspenders, belt or a cuff at the wrist; if there has been a previous lesion, pus from it may remain on the clothing, to be rubbed in somewhere else

A furuncle usually is caused by a staphylococcal infection in a hair follicle. The lesion begins singly about the neck, under the arm or in some other hairy portion of the body, and is first a central small pustule surrounded by inflammatory induration. Almost from the beginning the lesion is painful and tender The furuncle inspired the original classical description of an acute localized infection, namely, rubor, tumor, calor and dolor. Boils or furuncles destroy the follicles and on healing leave scars A furuncle is distinguished from a carbuncle by the fact that a furuncle has only one opening, whereas a carbuncle has multiple openings.

Metastatic infection in bones, kidneys and other distant points is not a rare complication of furunculosis; it occurs, however, in a relatively small proportion of cases. It is probable that pressure, squeezing, incision or other trauma to furuncles produces a transient bacteremia, which in turn results in metastatic abscesses (see the Fevers, Chapter 17).

Carbuncles often are caused by streptococcal infection. They are much larger than furuncles, are painful, and often cause fever and leukocytosis. Frequently they occur on the back of the neck and occasionally on the upper lip Owing to the peculiarities of the lymph drainage of the upper lip and the lower part of the nose, furuncles and carbuncles situated here are particularly dangerous because extension of the infection may enter the subdural spaces almost unhampered. Both furuncles and carbuncles may be the initial foci of infection which is spread by the blood stream to the heart, lungs, pleura, peritoneum, meninges and bones.

Hidrosadenitis is the term sometimes applied to axillary and inguinal affections by furuncles. The axillary lesions do not always suppurate and often are of the type called blind boils. The affection may extend to all of the axillary skin and subcutaneous tissues There may be difficulty in examining the area properly owing to the difficulty and pain caused in attempts to abduct the arm from the side

The prognosis in all the acute skin lesions caused by the staphylococcus, and in some infections due to the streptococcus, depends on understanding the normal progress of the lesions. The defensive cellular reactions initiated in the skin and subcutaneous tissues lead not only to the formation of pus but to an effective barrier or wall around the region of infection which prevents its extension. The collection of pus is shut in by this protective wall, occupies the center of the necrosed follicle, and forms the core of the boil. The lesion should be allowed to burst at its weakest point, or at most the weakest point lanced, and the contents and core allowed to evacuate spontaneously, a process which leaves a more or less aseptic cavity. Healing quickly ensues if the barrier has not been cut through by a knife or pierced deeply with a lancet At most, superficial lancing is all that should be permitted

Sycosis vulgaris is a chronic superficial folliculitis affecting mainly the beard. The infection may be most intractable It is maintained not by chronicity of the individual lesions but by their constant repetition The disorder may persist for years with little or no loss of hair, indicating that the hair roots have not been involved However, too much emphasis should not be placed on the superficiality of the lesion, for at times epilation of the hairs of infected follicles is not painful, indicating that the follicle is affected Owing to the chronicity of the infection, there are general redness and thickening of the affected region of the skin The presence of a chronic pustular inflammation of the hair follicles, limited to a hair-bearing area, especially the beard, is often sycosis vulgaris

The three common affections of the beard are impetigo, which clears quickly; tinea, more chronic, and sycosis vulgaris, which often lasts for years

Seborrheic sycosis, or sycosiform dermatitis, is not limited, like sycosis vulgaris, to the beard The beard of men and the eyebrows and eyelashes of both men and women may be affected Affections of the eyebrows and eyelashes are common. The infection begins after the age of puberty and produces painful swollen red eyelids and eyebrows The eyes matter and often are difficult to open on arising in the morning

On examination a chronic blepharitis with loss of eyelashes is present The blepharitis may appear after the dermatitis or may never be noticed There is a patchy dermatosis, a mixture of folliculitis with red, scaly dermatitis, spreading beyond the hair margin Similar patches occur on the upper lip, in the grooves of the lower lip and chin, and under the chin A distinct hypertrophy of the skin in the affected areas may be present. These patches are often persistent, lasting for years without a change in size

Granuloma pyogenicum is staphylococcal in origin. An injury has allowed the staphylococci to enter The lesions are on the fingers, at the nail fold They are small, red, shiny, pedunculated swellings composed of granulation tissue which bleeds easily

Streptococcal dermatitis is a superficial inflammation of the skin characterized by an acute onset of redness, thickening of the skin, and an abundant exudation of serum. In either the localized or the generalized forms of the disease the folds of the body, especially those behind the ears, and the scalp are more profoundly and frequently affected than other regions of the skin. As the inflammation subsides, there is formation of fine lamellar scales.

Erysipelas begins at one point on the skin of the face or neck and spreads rapidly, with a well-defined edge, from this point. The lesion is inflamed, hot, tense, shiny and painful. Secondarily occurring over this patch may be vesicles. If vesicles do not form, there is no subsequent scaling of the skin Erysipelas is always a serious disease Its prognosis is bad in the aged and the debilitated (see Chapter 17)

Impetigo contagiosa in some instances seems to be due to the streptococcus, and in others to the staphylococcus The vesicle, if cultured in the early stage, may yield streptococci or staphylococci It may be argued that the staphylococcus is either the primary or the secondary invader Children are most frequently affected, since infection is spread from clothing and contact Isolation of these patients should be mandatory

Superficial areas of the horny and the malpighian layers of the skin are the only parts involved. At first there are vesicles filled with clear fluid. The fluid becomes cloudy and the vesicle ruptures. Crusts form which are composed of dead epithelium, inspissated serum, leukocytes, fibrin and cocci. When these crusts are shed, the papillae are not exposed, and there is no bleeding. Healing is rapid and complete.

Examination reveals yellow crusts and vesicles situated mainly around the mouth, the cheeks, ears, and occasionally on other parts of the face. In the more severe infections the scalp and the fingers are involved. Often there are pinkish macules, indicating areas where the crusts have been shed from the face and scalp Pediculosis capitis may initiate the scalp infection and cause the spread and continuance of sporadic cases of the disease

When the fingers alone are affected, the lesions spread peripherally and for this reason may resemble a similar type of lesion on the face (*impetigo circinata*) which looks like ringworm. The reason for this resemblance is that healing of the bulla begins in and proceeds from the center. At the periphery the infection remains active, spreads and gives rise to a crusted, circular lesion which increases in size.

Impetigo neonatorum (pemphigus neonatorum) is a streptococcal infection which occurs in infants and is characterized by bullae about the mouth and fingernails The disease is not pemphigus

Impetigo is highly infectious. Not infrequently epidemics of the disease break out in lying-in hospitals The disease is often contracted by the mother On her the bullae appear about the breasts or places of contact All precautions are employed to prevent dissemination of the infection, such as thoroughly washing and sterilizing clothing, dishes, drinking cups, and feeding bottles All who attend these patients wash their hands thoroughly after the examination, before handling any objects

The diagnosis is based on the appearance on examination and on a recent occurrence of the disease in the institution or neighborhood The disorder is differentiated from chicken pox, pemphigus, dermatitis herpetiformis, dermatitis or eczema, and tinea circinata.

Impetigo barbae is a refractory form of impetigo which spreads rapidly and proves refractory to treatment This disorder is limited to the bearded regions and is characterized by the ease of epilation, followed by a drop of pus The disease is contracted in unsanitary barber shops

Infective intertriginous dermatitis or a similar disease may be caused by streptococci or other organisms The commonest sites of this disease are the folds behind the ears, with or without extension to the scalp Parts of the horny layer of the

skin are removed irregularly, leaving a raw area. The fold is thus rendered red and wet, while the scalp may be dry and scaly. Despite careful handling when the ear is moved forward to permit inspection of the fold, the thickened, swollen epidermis may crack and bleed. The disease is characteristically chronic and will return until all foci in the scalp have been eradicated

Acute infective dermatitis may result from various organisms. The lesions are asymmetric, superficial, well-defined, erythematous, vesicular, pustular, scaly patches. The margins of the lesion are undermined; the horny layer is raised as a scale with its free edge toward the center of the lesion It may not be possible to culture the causative organism.

Chronic dermatitis is common. There are three important conditions which occur in association with chronic dermatitis, namely, varicose veins; injuries to skin, nerves or blood vessels; and discharging wounds.

Varicose dermatitis is a common type of infective dermatitis In varicose dermatitis the inner surface of the lower third of the legs is affected As the disease progresses, ulceration develops which leads, when healed, if healing takes place, to the formation of rigid bound-down scars These scars may encircle the limbs by a hard fixed cuff of skin and subcutaneous tissue which further impedes the venous circulation

A dermatitis encir [illegible] sinus often occurs. The dermatitis is severe if [illegible] the sinus.

Dermatitis may fo [illegible] hands or other exposed parts, particularly if the injury has required long bandaging and dressing with salves The injury may be from any cause, but often there has been a puncture wound or injury to the underlying tissue as well as the skin A dermatitis which is difficult to heal may attend injury of a trunk of a peripheral nerve.

Infectious eczematoid dermatitis is distinguished by pustular and impetiginous lesions, perhaps due to the staphylococcus but more frequently to several and usually indeterminate organisms Inappropriate treatment often irritates this sort [illegible]

[illegible]

sodium hydroxide, for fungus will help to limit the etiologic possibilities Often the lesions will clear up if treatment other than cleanliness is discontinued

Acne conglobata is characterized by hypertrophy of the skin which accompanies the lesions of acne This hypertrophy is most noticeable about the nose, on the neck, back and buttocks These hypertrophic skin lesions of acne may become granulomatous and may form freely discharging sinuses, often deep and extensive. They may partially heal On each reactivation of the draining sinuses a generation of furuncles may occur These sinuses may resemble those of a tuberculous infection or one of the mycoses, such as sporotrichosis. In a patient of middle age a rapid increase in the area of induration around the sinus without other evidences for a [illegible]

[illegible]

These lesions may persist for weeks or months after perhaps a mild diphtheria

When a diphtheritic ulceration is suspected, smears and cultures from the lesions are taken at once, and if diphtheroid bacilli are found, antitoxin should be administered Virulence tests of the organisms may be made in order to arrive at a definite diagnosis

Tuberculosis. Tuberculosis of the skin is a serious but fortunately a rare disease Three women suffer from the disease for each man so affected. The disease is one of youth, before the age of 20 years It is acquired through contact, by an extension of an internal infection or by blood-borne infection

The tuberculous lesions on or about the nose and face are contracted by the direct spattering on the skin, from coughing or sneezing, of saliva or mucus which contains tubercle bacilli The postmortem wart occurring on the hands of pathologists is also an example of infection from contact. Butchers too may contract similar lesions from infected cattle

The skin over infected and caseating lymph nodes and around the sinus from tuberculous osteomyelitis may be infected.

Tuberculous septicemia may cause skin lesions over the body as a part of the miliary process. Miliary tuberculosis of the skin often appears suddenly during the course of pulmonary or bone tuberculosis and during convalescence from one of the exanthemas such as measles.

Tuberculosis of the skin, except for miliary tuberculosis, is a chronic disease The lesions progress by centrifugal spread. There are central healing and scarring while the periphery is active and slowly spreading The patient who has tuberculosis of the skin may die at an old age with the disease still active if there are no other active foci present in the body. When other active foci such as an active pulmonary tuberculosis or tuberculosis of the bone are present, the prognosis is that of the original infection The skin lesion may clear up and leave the other foci active.

For the purposes of description tuberculosis of the skin is usually divided into three forms, namely, (1) lupus vulgaris, (2) scrofuloderma and (3) miliary tuberculosis

Lupus vulgaris, or tuberculosis cutis luposa, is characterized by a great degree of chronicity It seems to be an inoculation type of tuberculosis which occurs on the head, face, nose, upper lip, cheeks, ears and neck of children from 4 years to 10 years of age The lesions are thus distributed because it is obtained from small droplets of tuberculous sputum disseminated in the air by coughing or sneezes of a tuberculous individual.

The process and the subsequent scarring may cause contracture of the mouth; destruction of the soft parts of the nose with necrosis of the cartilage, leaving a flat gaping orifice to the posterior nasal cavity; ectropion and, perhaps, blindness through corneal irritation and subsequent scarring, or loss of the auricles, by destruction of the soft parts and subsequent necrosis of cartilage

The usual lesion is a nodule from 2 to 5 mm in diameter It is raised, or it may lie on a level even with the surface In consistency it is softer than the surrounding skin, so that a blunt point drawn across the nodular area sinks as if crossing a hole in the skin In color the lesion is a light brown, clear and almost transparent The characteristics of the lesion are better observed if a glass slide is pressed firmly over it in order to expel the blood from the part The nodules often coalesce so that a larger area of affected skin appears which is actually one lesion There is a tendency to heal behind the spread of the lesion, and healing leaves irregular scars The mucous membranes frequently are involved.

Examinations of the lungs roentgenologically and of the urine and the sputum microscopically and by means of guinea pig inoculation for tubercle bacilli are important diagnostically A positive skin reaction to tuberculin seldom is helpful; if the reaction is negative, it rules out tuberculosis. The diagnosis depends on a skin biopsy However, in a young person the demonstration of the clear brown or reddish chronic nodules characteristically distributed on the face, nose and lips, accompanied with scarring and secondary epithelial changes leading to crusted warty forms, is usually sufficient for a diagnosis of lupus vulgaris. The prognosis is bad The disease persists throughout life.

Scrofuloderma (scrofula) is a direct infection of the skin from tuberculous lymph nodes of the neck or other underlying tuberculous infection. Draining sinuses develop and the adjacent skin is inflamed, swollen and cyanotic. Syphilis, for practical purposes, is ruled out if the serum reaction is negative

Miliary tuberculosis of the skin is but a part of the disseminated tuberculosis. It is a terminal manifestation of the disease elsewhere. Small papules appear which soften and ulcerate, and if life is prolonged the papules spread and coalesce and form ulcers. These lesions may occur about the mucous orifices without general distribution as a result of direct inoculation from infected discharges. The diagnosis is obvious.

SYPHILIS OF THE SKIN

n important cause of skin disease. In tropical ne cause of much suffering

lesions of syphilis become manifest during the first year after birth The important lesions of congenital syphilis are enumerated as (1) interstitial keratitis, (2) Hutchinson's teeth and (3) labyrinthine disease (see Diseases of the Lens, Chapter 4)

The skin lesions consist of a wrinkled, loose-appearing skin which has been described as old-mannish in appearance A pemphigoid or papular eruption may be present on the palms and soles and over the legs. The bullae of the pemphigoid eruption are of longer duration than those of impetigo neonatorum The papular lesions are commoner in the anal and the genital regions than on other parts of the body These papules may be erythematous in appearance and may closely resemble those of acquired syphilis

Often neither parent of a congenitally syphilitic child will admit knowledge of a syphilitic infection The physician is in turn interrogated concerning two possible sources of the child's infection. (1) Could it have come from the child's grandparents? (2) Could syphilis have been accidentally acquired? The answers are: (1) Congenital syphilis is from the mother to the child (2) Accidental infection occurs, but usually syphilis is acquired as are all venereal infections, and that is by direct contact, which is usually through sexual intercourse. However, accidental inoculation may occur through a breach in the skin or in a mucous membrane by such means as infected vessels for eating and drinking, infected instruments, especially the tattoo needle, kissing infected persons, droplet infection, of a physician's eye during examination of a syphilitic throat, or direct infection of a finger during the examination of a patient In some instances an admission of these means of acquiring syphilis may save much time for the physician. However, in reality the physician should realize that it may not be too important how syphilis was acquired if the patient has it.

skin is thickened and inelastic.

Acquired Syphilis. The *primary lesion* (hard chancre) appears from 2 to 6 weeks after infection If no ulceration has occurred, there is a hard, raised, red papule, the surface of which is glazed, moist, and bleeds on being traumatized If the primary sore is on the external genitalia, the patient always ascribes it to

manent after ulceration The regional lymph nodes are enlarged early The primary lesion may be small, may last only a week or two, and is described as just a pinpoint sore

The diagnosis is confirmed by the presence of the treponema in serum from the lesion on examination under darkfield illumination Positive results of serologic tests are not present for several weeks.

Extragenital chancres occur around the fingernails, the face, lips, cheeks, mouth, breasts, abdomen, and in fresh tattoo injuries of the skin.

The *secondary lesions* of syphilis are general surface lesions and skin eruptions In many instances the skin lesions of syphilis may be precisely described as macular, papular and nodular syphilides.

Symptoms referable to the body as a whole, or general symptoms, vary in degree and are not predictable There are often a feeling of ineptitude, pains through the body affecting the arms and legs, and headache which occurs at night after the patient has retired to bed There may be a low-grade fever during the evening hours In an occasional instance there are high fever and skin eruption which spreads rapidly, causing a serious disability. This is the so-called malignant syphilis. These rapidly developing secondary lesions of syphilis occur over the body and involve the mucous membranes as well Involvement of the mucous membrane by syphilis may be severe, with ulceration and deep sloughing of the tonsils and nasopharynx

A syphilitic eruption usually commences as a macular erythematous eruption over the abdomen, trunk and face The eruption of syphilis is commonly present on the palms of the hands and on the soles of the feet In the beginning it is truly a macular eruption. There is no itching The eruption varies in color and intensity and may simulate that of measles and of influenza. The color of a syphilitic eruption has often been described as coppery or fawn The lesions are in, not on, the skin

The *macular syphilid* is a common macular lesion that occurs on the body This lesion often commences around the umbilicus and from this part spreads over the thorax and the flexor surfaces of the extremities; it occasionally extends to the neck, but rarely to the face. The average diameter of the lesions is about 1 cm The edges are ill defined The lesions are at first a light yellow, which changes to a reddish color. There is no itching, and no scaling Usually there are other symptoms of syphilis present, such as the scar of the initial lesion or chancre. There also usually are enlarged lymph nodes in the posterior triangle of the neck and in the axillary, epitrochlear and inguinal regions. Alopecia may be present Sore throat and general aches and pains may be present, and in women there may be a history of miscarriage

There are two forms of *papular syphilid* One form, the small papular variety, usually occurs over the flexor surfaces of the extremities As a rule, the lesions are grouped. The papules are small and discrete, may be slightly scaly, and sometimes are associated with pustules On palpation the lesions can be felt situated in the corium The second form, the large papular variety, may occur on the face, neck and genitals as flat papules, often clearing up in the center, thus sometimes being designated as an annular type of syphilid These lesions are sometimes scaly, almost always accompanied by induration, and usually by other symptoms of syphilis

The *nodular syphilides* in syphilis are late secondary or tertiary lesions. These nodules may begin as millimeter-sized papules which are well defined Frequently they are multiple, two or more in number. The individual syphilid is firm and smooth, and reddish in color. As the disease advances, the nodules increase in size, ulcerate, and have the so-called punched-out appearance that is characteristic of syphilitic ulcers. These lesions often accompany other symptoms of syphilis. They are painless.

During the secondary stage of syphilis the serologic reactions are positive

A large papular eruption of syphilitic skin lesions may closely simulate lichen planus Lichen planus is itchy and occurs on the palmar surfaces of the wrists, the inner aspects of the knees, and the legs below the knees.

Both psoriatic lesions and syphilitic lesions may be circinate. Psoriasis is a disease of long-standing and recurrent manifestations, whereas syphilis is a disease of recent manifestations and rapidly spreading lesions and involves the true skin.

Leukoderma frequently occurs about the region of the neck and is accompanied

with pigmentation around the characteristic small white areas. Stubborn patches of pinta and syphilis about the face and neck, often lasting for years, simulate the lesions of chronic psoriasis or tuberculosis A unilateral psoriatic-appearing lesion on the buttock, calf or sole should be regarded with suspicion. The ringed and horseshoe manifestations of syphilis may resemble psoriasis or ringworm, but neither of these diseases affects the true skin.

The serologic tests for syphilis are now most reliable and diagnostically dependable. However, there is a possibility of false positive serologic reactions. In all questionable instances of these reactions a decision about validity of the test usually can be made from the history and the findings. All false positive and serologic fast-reactions should be checked by examination of the cerebrospinal fluid.

INFECTIONS OF THE SKIN DUE TO VIRUSES

Eczema Herpeticum. Kaposi's varicelliform eruption and Juliusberg's pustulosis vacciniformis acuta are synonymous names for eczema herpeticum.

Eczema herpeticum is due to the herpes simplex virus and occurs in children who, as a rule, already have an eczema. In the majority of cases, according to Barton and Brunsting, this eczema is a primary herpetic infection and as such is accompanied by a severe systemic illness which occasionally is fatal. A less severe form of the disease is observed in those who have circulating antibodies in the blood In these patients there is often a history of contact with a manifest infection by herpes simplex

The close association with atopic eczema may implicate the virus-potentiating activity of histamine, or the wide expanse of denuded skin so common in these patients may merely provide a good nidus for exogenous infection with the virus The disease may resemble eczema vaccinatum

The vesicles develop rapidly, in large numbers and in successive generations, for 3 or 4 days to a week The largest number of the varicella-like vesicles occur on the already eczematous skin A small number of grouped lesions appear on the intact skin. Those which appear first undergo desiccation, rupture, and expose the corium or they become encrusted and shed The outcome in the majority of cases is favorable

The diagnosis can only be suspected clinically and is established with certainty by demonstration of the virus by viral technics

Varicella-Herpes Viruses. The similarities of varicella and herpes zoster lie in the nature of their viral agent (*Briareus varicellae*), their vesicular eruptions, and their intranuclear inclusion bodies, while their greatest differences are found in age incidence, epidemiology and changes in the central nervous system; hence their widely different symptomatology (see Viral Infections, Chapter 17)

Varicella, or chickenpox, sometimes also called herpes zoster, zona, shingles or zoster, is a mild communicable disease caused by a virus similar to that which induces herpes zoster *Herpes zoster* is an affection limited to the cutaneous distribution of a cutaneous nerve

Varicella (*Ch*[illegible]) Th[illegible] [illegible]eks
In 24 hours after [illegible] or
accompanied with [illegible] and
trunk, spreading in some cases to the mouth and pharynx and extremities. In chickenpox the lesions are usually most abundant over the trunk, as contrasted with the face and extremities in smallpox The eruption occurs simultaneously with the fever, and its duration is proportional to the height and persistence of the fever.
[illegible]

Vesicles on the laryngeal mucosa, about the eyes and genitalia and in the hair may become infected secondarily and cause much discomfort.

On occasion an encephalitis, symptomatically similar to that accompanying herpes zoster and measles, complicates chickenpox. Patients usually recover from chickenpox encephalitis

Verrucae (Warts). Warts are small, benign papillary overgrowths, which vary in size, color and shape They occur slightly more commonly in women than in men. Certain families seem to have a relatively greater susceptibility to infection than other families. Warts are auto-inoculable and transmissible and may disappear without treatment There are four distinct types according to Lane. verruca vulgaris, verruca plana juvenilis, verruca plantaris and verruca acuminata.

The abnormal cellular hypertrophy is due to a local infection with a virus. Whether separate viruses cause the four different forms of verruca or whether the different forms are clinical variations resulting from one virus is unknown Rudloff expressed the belief that venereal vegetations and verruca vulgaris are sister growths due to the same filtrable virus, which manifests itself by papilloma formation on mucous membranes or on thin skin and by wart formation elsewhere.

Verruca vulgaris is the commonest type. These warts occur predominantly in children and adolescents and appear most often on the exposed areas, particularly on the hands and fingers, but any portion of the skin surface may be involved Variants of this type are the threadlike filiform wart of the eyelids and face and the digitate warts which project from the scalp, face and neck.

The lesion of verruca vulgaris is a raised, circumscribed, solid, round, gray or yellowish gray papule varying in size from 2 to 10 mm. The surface at first is flat and smooth but may become scaly, crusted, or fissured The warts may be single or multiple; frequently there is a primary mother wart, which in time is joined by satellite lesions

Verrucae planae juveniles, known as flat warts, are slightly raised, small, flesh-colored, round or angular papular lesions which are distributed over the face, neck, hands and wrists Almost universally multiple, these lesions occur most often in children and young women They may resemble vesicles or may closely resemble the papules of lichen planus and, rarely, those of molluscum contagiosum. They produce a dirty appearance on the face when they have coalesced and are situated on the chin

Verrucae of the plantar type occur on the padded areas of the soles and heels, less frequently the sides of the feet, the under surfaces of the toes, the palms and palmar surfaces of the fingers There may be a single wart, but often there are small satellites in the vicinity of the original lesion Differentiation from a callus and a clavus may be difficult but is facilitated by paring the surface of the verruca A wart is revealed as a well-defined, discrete, gray, round or oval area often containing small dark specks or threadlike lines, which are deposits of blood pigment If the surface of a callus or corn is pared, a smooth, hard, yellow growth containing no blood stains is seen

A variant of the plantar wart is the so-called *mosaic wart,* which has been well described by Montgomery and Montgomery as a warty patch, horny and granular with an irregular border, and varying in width from 1 to 10 cm Comparatively painless, the patch is situated under the pressure points and may extent onto the toes and behind the heels. It is often mistaken for callus. Paring reveals the intracellular nature of the patch, which consists of many small individual cores so closely grouped that they resemble a mosaic pattern The pain and tenderness of plantar warts may be sufficient to hamper the activities of the patient seriously.

Verruca acuminata, known also as condyloma acuminata and venereal wart, occurs chiefly on or about the genitalia and the anus, in the axillae and groins and on the navel. As single or multiple, discrete or confluent, raised, filiform or

papillomatous lesions, whose surfaces are often moist and macerated from the secretions of the surrounding organs, they are attached by broad or narrow bases. Verrucae acuminatae may be sensitive, painful and malodorous and may interfere with function

Warts may be difficult to treat successfully Many patients are convinced of the therapeutic virtues of witchcraft for the cure of warts.

INFECTIONS OF THE SKIN DUE TO HIGHER PLANT ORGANISMS
(*The Superficial Mycoses*)

Fungi, microscopic members of the plant kingdom, belong to phylum Thallophyta, orders Algae and Fungaceae. The order Fungaceae comprises bacteria (Schizomycetes), true fungi (Eumycetes) and slime molds (Myxomycetes). The Myxomycetes are nonpathogenic Of the four subclasses of true fungi the Hyphomycetes (Fungi imperfecti) contain the common pathogenic fungi present in lesions of the skin and hair. A skin fungus which does not invade the hair follicle is termed *Epidermophyton* Sabauraud called the fungi which proliferate on the surface of the hair Microspora: the two groups (Trichophyta) which invade the hairs are endothrix and ectothrix, depending on the situation of the spores in relation to the shaft of the hair.

Ringworm. Ringworm infection of the skin according to Lewis and Hopper is arbitrarily divided into regional varieties, namely, scalp (tinea capitis), beard (tinea barbae), smooth or glabrous skin (tinea glabrosa), folds of skin (tinea cruris) and feet and nails (dermatophytosis and onychomycosis)

Tinea Capitis (*Ringworm of the Scalp*). Tinea of the scalp usually is due to one of two Microspora, *Microsporum audouini* and *Microsporum lanosum*

However, both the *Trichophyton* and the *Microsporum* group have (1) species which are pathogenic principally for certain lower animals (zoophilic) and (2) species which are pathogenic principally for human beings (anthropophilic).

Infections contracted from animals have two important characteristics; they are but slightly, if at all, contagious among human beings, and they either are self-limited or respond to topical therapy. Humans are poor hosts for this group of fungi, and, as Lewis and Hopper showed, the self-limited features of these fungi may be accounted for by the development of antibodies and the production of an inflammatory reaction in the neighborhood of the infected hairs

In the United States, *Microsporum lanosum* is the important animal (zoophilic) representative of the Microsporum group and is generally transmitted by cats or dogs Unlike the disease contracted from cattle, *Microsporum lanosum* usually produces but slight inflammatory reaction. Several members of a family may be infected from the same pet, but extensive epidemics do not occur. Infections produced by *Microsporum lanosum* must be differentiated from the epidemic form (*Microsporum audouini*) because they are self-limited and nonepidemic.

Infections with human (anthropophilic) fungi are contagious and are usually resistant to topical therapy The lack of antibodies and severe inflammatory reaction is ideal for survival of the fungus and allows infection to persist for years.

Microsporum audouini has been responsible for the recent rapid increase in ringworm of the scalp in the United States

Microsporum audouini may cause epidemics in institutional children When the condition is first discovered, there are several small areas in the occipital and temporal regions in which the hair is dull and broken off The surface of the patch is usually scaly Occasionally a considerable degree of inflammation may be present but this is not the rule The lesions spread peripherally, finally reaching 1⅕ inches (3 cm) or

more in diameter. There is little tendency for the infection to spread to other parts of the body.

Trichophyton violaceum develops insidiously and is widely dispersed over the scalp It invades the cortex of the hair, causing the hair to break off close to the scalp or just below the surface of the scalp which gives the appearance of an ingrowing hair. The disease may heal at puberty.

Microsporum lanosum causes a fungous infection of the scalp of children and occasionally involves glabrous skin. It may be, at times, contracted from pets (kittens). The initial lesion is frequently the largest There is loss and breaking off of hair in the affected patches with marked inflammation and *tenderness The duration of the disease* is only a few months

Microsporum fulvum resembles *Microsporum lanosum* except there is a tendency for the inflammation to remain localized to only one part of the scalp

Endothrix *Trichophyton causes favus Favus usually is a follicular involvement of* the hairs but it may occur with minimal follicular involvement. The disorder may spread to the nails or to the glabrous skin

On the scalp favus begins as a small area of scaly inflammation in which the hair follicles become festered Breaking of these small pus pockets results in yellow crusts which increase in size and finally become cup-shaped (scutula) The scutula are yellow, friable scabs pierced with hair. There is intense itching and a moldy odor like that of rats The hair of the scutula falls out The skin becomes atrophic and due to the spread of the disease an irregular permanent baldness ensues. Spontaneous recovery from the disease eventually occurs However, when there is a minimal follicular involvement, there is only a diffuse superficial but adherent scaling of the scalp, with little, if any, permanent alopecia.

Trichophyton gypseum is often contracted from pets and farm animals It may vary in intensity and distribution of its manifestation in accordance with susceptibility to it Widespread infections involving the hands, feet and face are due to increased susceptibility or increase in the virulence of the infective agent The characteristic lesion is a severe inflammatory reaction of the scalp and the development of kerion.

In many instances bacterial infections of the skin and fungous infections are both present This is particularly true of an infection like *Trichophyton crateriformi* When a mixed infection is present part of the manifestations—the crusting, kerion and shedding of hair—is caused by the secondary infection by bacteria and other fungi The treatment of the bacterial infection often suffices to effect a recovery.

In summary the manifestations of tinea of the scalp are partial loss of hair in *patches, breaking off and lack of luster of the infected hair, and varying degrees* of inflammation Atrophy and scarring may follow certain types of infection Kerion formation is common In appearance a kerion is a marked tissue reaction to the infecting microorganism, one of several species of fungi The pustular lesion is a painful, elevated, boggy, erythematous, localized tumefaction with simple scaling at the bottom.

DIAGNOSIS. The diagnosis of ringworm of the scalp may be made reasonably accurately by microscopic study of scrapings from the lesions, skin or hairs when properly prepared.

Patients who have ringworm of the scalp vary in their reaction to trichophytin, mainly in accordance with the type of infecting microorganism and with their own powers of resistance *There is usually more response when the fungus is also* pathogenic to animals.

A scalp infected with ringworm will show, under filtered ultraviolet rays, a characteristic fluorescent effect whenever infected hair is present. The ultraviolet rays are diagnostically important in revealing the presence and extent of *the ring*-worm infection of the scalp.

Tinea Barbae (*Ringworm Infection of the Beard*) Infections of the beard commonly are due to *Trichophyton gypseum* There are occasional instances of infections caused by *Microsporum lanosum, Trichophyton rosaceum, Trichophyton violaceum* and *Trichophyton purpureum.* The spread of these infections is thought

to occur in the barber's shop. Animals are known to be carriers of *Trichophyton gypseum* or *Microsporum lanosum* The disease may be contracted by contact with those who have infections of the scalp or of the glabrous skin. There are two types of infection, (1) diffuse inflammatory and (2) sycosis.

The diffuse inflammatory process is contracted from pet animals. The beard in the affected areas loosens and epilation is easy In the sycosis type of tinea barbae, once the infection is established, it slowly spreads as a mild crusted folliculitis with breaking off of the invaded hair (*Trichophyton violaceum*) or similarly without the formation of hair stumps (*Trichophyton purpureum*).

The diagnostic value of the reaction to trichophytin depends on the type of infecting organism. *Trichophyton gypseum* and *Microsporum lanosum* infections give definite positive reactions to skin tests In the other infections the skin reactions are irregular and cannot be depended on as tests of diagnostic value.

If the shaft of the hair has been invaded, a fluorescence of the infected hair is observed under filtered ultraviolet radiation. Endothrix organisms give the fluorescence. The ectothrix organisms produce no fluorescence under the filtered ultraviolet radiation The inflammatory type of tinea barbae has to be differentiated from sycosis barbae, iododerma or bromoderma, and syphilis.

Tinea Glabrosa (*Ringworm of the Smooth Skin*).—Fungous infections of the glabrous skin occur as scaly circinate patches, as solid plaques, or in geographic configurations

Microsporum lanosum (*M. canis*) obtained from contact with kittens or other pets or from an infected individual is the usual cause of ringworm of the smooth skin. Less commonly infection of the smooth skin extends or is carried from scalp infections (endothrix *Trichophyton*) or from feet infections (*Trichophyton gypseum, Trichophyton purpureum*)

Microsporum lanosum infection is manifested by an erythematous ringed lesion which may gradually increase to a diameter of 5 or 6 inches There are usually minute vesicles along the border, the surface is scaly, and the center appears unaffected Sometimes two or more concentric rings may appear in a single lesion. The lesions are commonly present on the faces or necks of children with tinea capitis The backs of the hands and other exposed parts are the usual sites of the first lesions in patients who catch the infection from an outside source. New lesions may develop on various parts of the skin, depending on extension and on transfer of the organisms from the original focus. The subjective symptoms are usually mild, although the infection is itchy and subsequent scratching may contribute to its spread

The eczematous type of smooth skin infection by tinea may simulate in appearance almost any form of dermatitis The primary eczematous type is the initial response to infection (usually *Trichophyton gypseum*) In this form of eczematous dermatitis the first lesion (or lesions) is the vesicle, and vesicles continue to form, rupture and become crusted The infection spreads peripherally, there being no tendency to central clearing The lesions remain ill defined or become circinate, with active vesiculation along the periphery.

The secondary type of eczematous dermatitis from tinea is caused by medicaments or by treatment producing primary irritation, which transforms the circinate lesions into vesicular, oozing patches surrounded by varying degrees of dermatitis.

Trichophyton purpureum may cause a large surface eruption of skin of the trunk The infection begins at one or more points and migrates in a thin line over an ever-widening area. The affected skin is dull red and presents a slight infiltration and scaling on the surface As the border of the lesion advances, behind it the skin is lighter owing to loss of color. Persistent itching is a constant symptom.

The diagnosis is usually established by cultural methods from the skin lesions.

Fungi are absent in material taken from the lesions. The trichophytin reaction is usually negative in cases of uncomplicated tinea of the glabrous skin

The prognosis varies with the infecting microorganism Ordinary tinea circinata usually responds to treatment within a week or two The eczematous type takes longer to respond, endothrix *Trichophyton* infections still longer, and the infections due to *Trichophyton purpureum* are resistant.

Tinea Cruris (*Dhobie Itch*). Tinea cruris is a superficial fungous infection (caused chiefly by *Epidermophyton floccosum* and species of *Trichophyton*) confined usually to the medial surface of the proximal third of the thighs, although other parts of the skin may become affected. The infection may be obtained from contact or from infected articles of clothing Another form of the disease is a contact dermatitis of various causes, in India it has been attributed to the marking fluid, bhilawanol oil (from *Semecarpus anacardium*, of the family Anacardiaceae), used on laundry by the native washermen (dhobie). Tinea cruris at times may assume epidemic heights.

The eruption is usually bilateral and symmetric, it favors the upper inner portions of the thighs but may extend up to the pubis and as far back as the sacrum The axillae, the umbilicus, the inframammary areas and the interdigital webs of the feet are occasional sites of the infection. Vesicopustules are sometimes seen on the soles. The friction of clothing during hot weather causes varying degrees of secondary eczematization

The area of the rash is well marginated by a border of minute vesicopustules The surface is scaly and there is little or no tendency to central clearing The lesions are brownish red.

The absence of evidence of tinea infection of nails, hair, feet or smooth skin elsewhere over the body limits the likelihood of other tinea infection.

Tinea cruris usually does not initiate sensitization to trichophytin A test with trichophytin usually elicits a negative or a mildly positive reaction. With *Trichophyton gypseum* a positive reaction is usual, but when *Trichophyton purpureum* is the causative fungus, a negative reaction is common.

The ordinary form of the disease usually responds readily to medicinal applications but tends to relapse. The lesions caused by *Trichophyton gypseum* are likewise readily cured, but those due to *Trichophyton purpureum* are extremely obstinate.

Dermatophytosis. The term dermatophytosis refers to a superficial fungous infection of the skin The disease (sometimes called athlete's foot) is usually acquired by transfer from organisms affecting the hands, feet or nails.

Dermatophytosis is a common disease It is commonest in boys and men from 15 to 25 years of age Hyperhidrosis is commonly present in those who have dermatophytosis

Some lesions of the feet and nails resemble dermatophytosis of fungous origin but may be due to causes other than fungous infections. If the dermatophytosis is due to a fungus, *Trichophyton gypseum* and *Trichophyton purpureum* can be cultured from the lesions *Microsporum albicans* and *Microsporum lanosum* may occasionally be present

There is an acute inflammatory type of the disease due to *Trichophyton gypseum*, and a chronic type, due to *Trichophyton purpureum*.

The inflammatory type (*Trichophyton gypseum*) commences on the feet and is manifested by vesicles between the toes or on the soles. The skin between the fourth and the fifth toes is very commonly affected The vesicles, or bullae, rupture and the skin at the site of the lesion becomes macerated, soggy and white. This appearance may be maintained for weeks, months or years On peeling away of the soggy white debris of skin, fissuring and cracking and erythema occur

During the hot weather there may occur a pruritus of the toes, some swelling, and the appearance of vesicles on the soles and perhaps on the sides of the toes and

feet. Synchronously with the evidence of local inflammation on the feet, vesicles may appear on the palms of the hands and sides of the fingers. These eruptions are due to the dissemination of products of fungi through the blood stream, and the lesions are known as dermatophytids. They are sterile on culture.

In instances in which there is an increased sensitivity the eruption may spread to involve the intertriginous areas and folds of the upper parts of the thighs, the *perianal region, the axillae, the inframammary regions and the umbilicus* A secondary infection of the involved areas by pyogenic organisms is common. This secondary infection may overshadow the characteristics of the fungous disease and appear as an eczematoid dermatitis

Infection of a nail with *Trichophyton gypseum* may be superficial, causing only a white patch on the surface or in the substance of the affected nail (leukonychia trichophytica). A more severe infection causes the nail to turn pale yellow, opaque, lusterless and friable, and separation of the nail may occur Subungual hyperkeratosis and uneven dystrophic changes in the nail are frequent, but paronychia is rare Mild to severe pain may occur

The appearance of the eruption (with itching) on the feet and on the hands is peculiar to *Trichophyton purpureum* infections. Lesions of the feet and hands may occur on the soles and palms, the sides, the dorsa, the toes and fingers or the nails

Of patients who have *Trichophyton gypseum* infections, about 7 of every 10 give positive reactions to skin tests with trichophytin in 48 hours, of those who have *Trichophyton purpureum* infections about 3 of each 10 give positive reactions after 48 hours Reactions to the trichophytin skin test in those who have dermaphytosis from other organisms are so irregularly present that the value of the test for purposes of diagnosis is doubtful

The diagnosis is made by culture and identification of the offending organism. In most cases of inflammatory tinea the reaction to the trichophytin test is positive. When *Trichophyton gypseum* is the causative fungus, the prognosis is hopeful If *Trichophyton purpureum* is the offending microorganism, cure is difficult The duration of the infection and the extent of involvement of the skin are often determinative factors in the prognosis.

Tinea Versicolor (*Pityriasis Versicolor, Chromophytosis*). The microorganism, a species of fungus, that causes tinea versicolor is known as *Malassezia furfur*. The disease affects adults of both sexes. The lack of personal hygiene sometimes seems to be a predisposing cause in many instances of the disease

The disease manifests itself by light yellow-colored scaly macules and patches starting from barely visible lesions in single or multiple foci. The sites of predilection are the thorax, the abdomen and the back At times the eruption favors intertriginous locations but it may involve large stretches of skin.

During the summer or autumn a patient who has tinea versicolor may exhibit apparently depigmented areas on the surfaces of the affected skin which are exposed to sunlight The patches occupy the sites of lesions of tinea versicolor. Their color is not the pale white, with demarcated edges and with increase of pigment at the periphery, as is present in vitiligo The condition appears year after year, and despite becoming less noticeable during the winter it will reappear during the summer

The lesions of tinea versicolor under filtered ultraviolet rays reveal a fluorescence Examination for fungi, combined with observation of the patient under filtered ultraviolet radiation, is diagnostic The ordinary form of tinea versicolor is not confused with any other disease

Erythrasma. Erythrasma is a superficial mycosis resembling tinea versicolor The causative fungus is *Actinomyces minutissimus* (*Microsporum minutissimum*). The means of transmission of the infection is unknown. The disease is less common

than tinea versicolor. Erythrasma is commoner in young men, whereas tinea is commoner in old men, and the lesions of erythrasma are limited to one or more in number, situated in the axillae, the groins, the intergluteal cleft or other intertriginous areas. The lesion commences as a small, scaly, well-circumscribed macule with a reddened border which gradually enlarges to form variously sized patches. The color varies through mixtures of red and brown, the exact shade depending on the amount of pigment in the skin, the age of the lesion (the older the darker) and the amount of sunlight to which the lesion has been subjected.

In all cases a mycologic diagnosis should be made by identification of the organism. The demonstration of the microorganism may be difficult

Otomycosis (*Myringomycosis*). Otomycosis affects the external ear and the aural canal. This condition may be due either to fungi or to streptococci. No age is exempt, although the majority of patients are young adults

The external ear around the meatus is swollen and red. A moist mass of debris fills the canal When this is removed, the affected skin is seen to be exudative. The disorder may extend down the canal and affect the drum.

Lepothrix (*Trichomycosis Axillaris*). Trichomycosis axillaris (*Actinomyces tenuis*) is characterized by nodes on the axillary hair, often with the formation of red or black pigment. Micrococci are said by some to be responsible for the formation of this pigment and not *Actinomyces tenuis*

Irregular concretions form in the axillae and attach themselves to the hair The attachment is firm, and the nodes (concretions) are difficult to dislodge The entire circumference of the hair is involved. The concretions are usually yellowish, red and black varieties are uncommon The concretions exhibit fluorescence under filtered ultraviolet rays.

Tinea Nodosa (*Piedra*) This disease, caused by *Trichosporon giganteum,* is manifested by small, hard nodes along the involved hair shaft The disease is confined to scalp hair of women in South America The European and Asiatic *varieties affect only the male beard and mustache, never the scalp.* The nodules of both varieties are stony hard and light or dark brown. From 1 to 25 nodes may be present on one hair. Shaving is a certain cure

Chromoblastomycosis (*Dermatitis Verrucosa*) Three fungi, *Hormodendrum pedrosoi, Hormodendrum compactum* and *Phialophora verrucosa* are recognized as causing verrucous nodules. The tissue reaction consists of granulomatous changes similar to those resulting from the presence of a foreign body, a tuberculoid reaction and miliary abscess formation.

The lesions are situated on the leg Each lesion commences as a verrucous nodule or an ulcer The nodule may be reddish, purplish or brownish. After many months or years verrucous masses are formed by coalescence of two or more lesions and their subsequent growth Growth continues until large pedunculated, fimbriated, cauliflower-like masses are formed Infection by bacteria causes a foul discharge and edema of the food and ankle. The lesions resemble psoriasis, lupus erythematosus and tuberculosis

Mycologic study and the results of inoculation of guinea pigs may reveal distinguishing features of this disease

Moniliasis. The causative microorganism of moniliasis is *Candida albicans* The organism is etiologically weak It does not occur on the normal skin. It is a common inhabitant of the orifices of the body and the gastrointestinal tract Once *Candida albicans* is established, it may cause either superficial or deep mycotic infections. *Only the skin infections will be considered here*

Housewives, bartenders, waiters and bakers appear to be more susceptible than other persons to the infection because of their occupational sweating and often-wetted hands When moniliasis (*Candida albicans*) infections are limited to a localized area of skin, they are termed the moniliid type

These localized affections of the *skin* are manifested by well-defined, bright red, exuding patches with scalloped borders occurring mainly in intertriginous areas. Bordering the zone of intertrigo, small flaccid vesicopustules may be present. A monilial intertrigo occurs in the axillae, the groins and the intergluteal fold The process may extend from a primarily intertriginous location to the flat skin, and large surfaces of skin of a susceptible person may be affected.

Candida albicans infections at the angles of the mouth may occur as rhagades or perlèche, the bases of which are bright red This type of perlèche cannot be easily distinguished from those types due to vitamin deficiency secondarily infected by streptococci.

Onychia and paronychia of the *fingernails* and occasionally of the *toenails* occur. Infection of multiple digits is the rule. Rarely is only one digit involved. As a rule, the paronychial tissues are the first to be affected A thin purulent discharge may appear under the nail fold Transverse ridges appear on the nail, though it remains hard. The nail gradually becomes thickened and distorted at the edges and may become yellow The natural glazed surface is unaffected. The edges of the nail may be eroded. There is no pain except by pressure on the nail and from the paronychia when dry

Thrush is a manifestation of *Candida albicans* It is most commonly seen in infants It may have been contracted at the time of birth from a *Candida albicans* vaginitis of the mother. A whitish, loosely adherent membrane is attached to the inner surface of the cheeks or to the palate and sometimes to other portions of the oral mucosa. The whitish membrane resembles the curd of milk and is distinguishable by the fact that it can be wiped away without leaving residual surface markings.

The presence of *Candida albicans* in the *vagina* usually does not indicate the presence of a *Candida albicans* vaginitis In women sufficiently susceptible the organism may produce pruritus and vaginitis accompanied with a thin vaginal discharge. It is even less likely that *Candida albicans* is of etiologic importance in *pruritus ani*

Moniliid lesions may occur as sterile vesicular lesions on the *hands* and localized or widespread erythematous vesicular exudative patches caused by dissemination through the blood stream of products of *Candida albicans*.

The diagnosis is difficult, for culturing of *Candida albicans* from a lesion does not identify the lesion as being caused by *Candida albicans* The disease no doubt occurs, but to make the diagnosis is a dangerous practice except when the lesions are around the nails of the hands Identical lesions about the nails may be caused by bacteria. The oidiomycin test is of no value in differential diagnosis. When infection is generalized, the outcome is often fatal (see Deep Mycotic Infections, Chapter 17).

CYSTS, SINUSES AND FISTULAS

Cysts, sinuses and fistulas are of common association with the cutaneous structures The commonest cysts are the epidermal cysts.

Anderson classified cysts, sinuses and fistulas as they are here described

Epidermal Cysts. Epidermal cysts have an epidermal lining but lack definite dermal structures Epidermal cysts are generally found in the cutis or corium and are only rarely situated below the cutis in the subcutaneous tissue. Occasionally, such cysts may be attached to the epidermis by a band of epithelial composition. The great majority, however, are not connected with either the overlying epidermis or any cutaneous gland or structure.

Degenerative changes occur with considerable frequency in epidermal cysts. Rupture of the epithelial capsule is common, and a foreign body giant cell inflammatory reaction ensues Fibrosis and relative involution may occur and, while calcification is frequent, true ossification is rare. Malignant degeneration may occur (*epithelioma*).

Sebaceous Cysts. Sebaceous cysts result from the occlusion of sebaceous glands, and hence their epithelial lining is composed of secreting sebaceous gland cells. The contents of the true sebaceous cyst are light yellow in color, homogeneous in consistency, and have a disagreeable, distinctive odor.

The multiple cysts occurring on the trunk in association with acne and seborrhea are true sebaceous cysts

Sweat Duct Cysts. Sweat duct cysts are associated with the sweat ducts and sweat glands and are generally termed hydrocystomas or sudoriparous cysts These cysts appear on the cheeks as solitary shiny, translucent and fairly deep lesions 1 mm in diameter Occasionally, larger ones occur on the upper eyelid The larger solitary lesions are best removed surgically, the smaller lesions can be destroyed by electrodesiccation.

Dermoid Cysts. True dermoid cysts are congenital in origin and are situated in areas where there was a connection with embryologic fissures and clefts They occur in the cutis or the corium. They may occur at either the inner or the outer canthus of the eye in relation to the bony walls of the orbit, or on the midline of the nose along the lines of closure of the nasal bones, or along the anterior midline of the neck

The history of a *dermoid cyst of the neck* is that of a midline swelling in the neck above the thyroid gland which has been present for years Either because of an increase in size or for cosmetic reasons the patient consults a physician. The diagnosis of a cyst or a mole is made and there is an attempt to treat the lesion either by electrodesiccation or by surgical removal A few hairs are generally removed at such times. There results a sinus opening which occasionally discharges cheesy material, pus and blood The conversion of the dermoid to a sinus opening therefore results from subtotal surgical removal, or at times may take place spontaneously.

These midline dermoids of the neck may grossly resemble thyroglossal duct cysts. Thyroglossal duct cysts are remnants of the embryonic duct which connected the thyroid gland to the tongue The remnant of the lingual connection in adults is the foramen caecum in its posterior dorsal surface Thyroglossal duct cysts may appear as cystic masses on the posterior dorsal surface of the tongue.

Mucous Cysts. The so-called mucous retention cysts, which are situated on the inner aspect of the lower lip usually opposite the cuspid tooth, are very common (see Chapter 4).

Traumatic Epithelial Cysts. Cysts resulting from trauma are caused by (1) displacement of epithelial islands, (2) stimulation of epithelial growth or (3) production of alterations in the normal structure of cutaneous appendages such as the hair, sebaceous and sweat glands.

A traumatic cyst occurring under the free end of the fingernail may cause moderate tenderness and even erode the terminal phalanx by pressure. Ossification may occur within the cyst and necessitate removal

Sinuses and Fistulas. A sinus is an open channel, tract or tube, blind at one end and communicating at the other with a cutaneous or mucous surface A fistula [illegible], or between a cavity [illegible] granulation tissue or [illegible], tract is, for example,

[illegible] [illegible]illimeter-sized slitlike openings of congenital origin occur on the lower lip If bilateral, there is one opening on either side of the midline. The sinus tracts are generally 1 to 2 cm long and [illegible] blind pocket [illegible] to be

familial and are often accompanied by other deformities such as cleft palate and harelip.

The solitary midline sinus occurring on the upper lip just beneath the columella of the nose is the external manifestation of a deeper-lying dermoid cyst.

Epidermal Fistulas. In their simplest form epidermal fistulas are seen about the face, neck, buttocks and inner aspects of the thighs and less commonly about the breasts and axillae The process either originates in the double comedones of a severe acne vulgaris or follows a process similar to hidradenitis suppurativa.

Congenital auricular fistula, sinus preauricularis and fistula auris congenita occur as small papules situated at the anterior border of the ascending limb of the helix. From such sinus openings there may be an occasional offensive discharge. At other times with the closure of the orifice a retention cyst may develop in front of the ear. Finally secondary infection may convert the sinus tract or cyst into a walled abscess which opens either spontaneously or by incision In either event a solitary granulomatous lesion anterior to the ear ensues. As the result of repeated infections many fistulous tracts develop in an extensive area of skin This fistulous area may present a lesion which resembles lupus vulgaris or actinomycosis

There is a frequent association of preauricular sinus, a developmental defect, with other congenital malformations such as branchial fistulas of the neck, hypospadias and congenital absence of the tear duct

Sinus tracts of dental origin are common and are often associated with an alveolar abscess at the root of a tooth, less commonly with syphilis of the mandible and rarely with adamantinoma of the jaw They may open on the chin, the cheek, the floor of the nose, near the orbit and on the buccal or lingual aspects of the gums or at distant sites, as the neck

On the lateral aspects of the neck, sides of the face, and as high as the lower part of the eye may occur cysts which are remnants of an incomplete closure of an embryonic branchial cleft

Diagnosis of Cysts, Sinuses and Fistulas. Aside from the clinical findings, visualization of the tract and cysts by means of roentgenograms after the introduction of radiopaque solutions is a helpful measure In some cases much evidence as to the place of opening of a fistula may be obtained by the injection of a solution of methylene blue

Surgical treatment of some of these lesions may be difficult. A final diagnosis awaits histologic studies

INFECTIONS OF THE SKIN BY HIGHER ANIMAL PARASITES

Helminths. The term helminths is used to designate wormlike animals of three diverse phyla (1) Annelida (segmented worms), (2) Nemathelminthes (roundworms), and (3) Platyhelminthes (flatworms) In medical parasitology all parasitic worms are collectively referred to as helminths.

Annelida. The segmented worms are mostly free-living. The ectoparasitic *leeches* comprise the parasitic members of this phylum

The chief predators of man and animals are the terrestrial leeches that live in damp tropical forests, where they attach themselves to anyone within reach Various species have been described in southern Asia, the East Indies, Australia, Oceania and South America Aquatic species attack bathers, examples of these leeches are those that are encountered in the swimming holes along some southern streams and elsewhere in the United States

The bite, usually unnoticed, is detected by the presence of blood or the engorged leech The wound, though painless, bleeds readily because of the anticoagulative secretions of the leech and heals slowly. Heavy infestations of man and animals may result in serious exsanguination. A number of cases of infestation of

the upper part of the respiratory tract and of the digestive tract from drinking water have been reported Leeches in these locations after narcotization may be removed with foreceps Those attached to the exterior of the body may be removed after application of vinegar or strong salt solution to loosen their hold.

Creeping Eruption (*Hookworm Disease, Ancylostomiasis*). In man the skin lesions of creeping eruption are caused by penetrations of the larvae, commonly known as hookworms, of at least three species of nematode worms of the family Ancylostomatidae (superfamily Strongyloidea). *Ancylostoma duodenale, Necator americanus* and *Ancylostoma braziliense.*

The eruption develops after contact of the patient with moist sand and earth contaminated by the feces of infected dogs, cats or human beings At the point of invasion a reddish, itchy papule develops; and within two or three days narrow linear, slightly elevated, erythematous, serpiginous, intracutaneous tunnels are produced by the migration of the larvae, which move from a fraction of an inch to several inches each day. Vesicles form along their course, and the surface becomes dry and crusty. The itching is intense, and the resultant scratching may lead to secondary infection. The commonest site is on the hands or feet, but the eruption may occur on any part of the body It persists for several days or weeks.

Dracunculiasis. The Dracunculidae are long slender nematode worms, filarial parasites The definitive hosts, other than man, in North America are the fox, raccoon and mink The species parasitic in man is *Dracunculus medinensis* of the family Dracunculidae

When the infected cyclops is ingested in drinking water, the larvae penetrate the wall of the digestive tract and migrate to the loose connective tissues When the female worm reaches the surface of the body, it liberates a toxic substance into the subdermal tissues, producing a local inflammatory reaction in the form of a subacute sterile abscess with serous exudation and formation of blisters.

The early manifestations of urticaria, erythema, dyspnea, vomiting, diarrhea, pruritus and giddiness are caused by the absorption of allergenic substances from the worm If the worm is broken during extraction and the larvae escape into the subcutaneous tissues, a severe inflammatory reaction with fever ensues, and if secondary bacterial infection occurs, formation of abscess, sloughing of the tissues and even fatal septicemia may result.

The local cutaneous lesion appears at first as a reddish papule with a vesicular center and indurated margin The blister contains a clear, yellow fluid. The worm *lies in a subcutaneous tunnel with its anterior end beneath the blister.* Its course may be marked by induration and edema *Contamination of the ruptured blister* by pyogenic bacteria may produce abscesses, cellulitis, and ulcers. At times the worm may become calcified and remain for years as a hard, twisted cord beneath the skin

Diagnosis is made from the local lesion, worm and larvae Dead or calcified worms may be located by roentgenologic examination. Treatment involves the extirpation or destruction of the worm. The prognosis is usually good.

Cercarial Dermatitis. The cercariae, which are larvae of certain species of animal schistosomes or flukes (Platyhelminthes), produce in man a cercarial dermatitis.

The cercariae of 6 species of animal schistosomes have been associated with cercarial dermatitis: (1) *Cercaria elvae,* (2) *Cercaria stagnicolae,* (3) *Cercaria physellae,* (4) *Schistosoma deuthitti,* (5) *Trichobilharzia ocellata* and (6) *Schistosoma spindale* The first four are found in the United States of America.

In the United States *Cercaria elvae* and *Cercaria physellae,* found in swampy waters, produce *collectors' itch. Cercaria stagnicolae,* which frequents the shores of lakes, is more often the cause of *swimmers' itch.* Persons in contact with aquatic vegetation are most likely to be infected with *Cercaria elvae* and *Cercaria physellae.*

The affected beaches are usually near vegetation that furnishes a favorable habitat for snails The cercariae swarm in the shallow water or are swept toward the shore by wave action. They survive about 24 hours

Cercarial dermatitis has been recorded in England, France, Germany, Switzerland, the Federated Malay States, Canada and the United States of America. In North America endemic centers have been found in Saskatchewan and Manitoba, and in Wisconsin, Michigan, Minnesota and Iowa. Outbreaks have occurred in Illinois, North Dakota, Nebraska, Texas, Florida and Washington

The cercariae adhere with the ventral suckers and enter in about 5 minutes through the action of their anterior spines and lytic secretions Penetration of the skin occurs when the film of water evaporates The cercariae may remain alive in place for a day but the reaction persists around the burrows They may be destroyed in the epithelial layers of the skin and become walled off. During these actions there is inflammatory response with edema.

As the water evaporates, a prickling sensation is followed by the rapid development of urticarial wheals, which subside in about half an hour leaving a few minute macules After some hours severe itching, edema and the transformation of the macules into papules and occasional pustules occur, reaching maximal intensity in two or three days. The papular and sometimes hemorrhagic rash heals in a week or more, but may be complicated by scratching and secondary infection. Individuals vary in susceptibility

THE DERMATOSES

The term dermatosis is all-inclusive It simply means a skin disease. The term toxic dermatosis is all-inclusive too, for it refers to any skin disorder referable to a toxic agent. Still more tolerance is required in the use of these terms, for there are (1) the dermatoses due to a known or a proved group of toxic agents and (2) the dermatoses due to unknown toxic agents

The known agents which may produce dermatosis are: (1) bacteria, (2) some higher plant and animal parasites, (3) viruses, (4) chemical agents and (5) physical agents These agents have different methods of attack Some are able to attack directly while others attack indirectly The latter group make themselves manifest through sensitization, acting as allergens on an individual predestined by inheriting the weakness of being easily sensitized (see Chapter 18).

The various dermatoses are mentioned in their relation to a disease or in association with a toxic agent or agents in various parts of this text.

ENDOCRINE DISTURBANCES OF THE SKIN

Seborrhea. A definite etiology has not been established for seborrhea.

At puberty the adult distribution and type of hair develop and there is an increase, and perhaps a change, in the quality of the sebaceous secretion These changes are synchronous with puberty and are thus attributed to functioning of the glands of internal secretion It is in early adulthood that dandruff begins to be troublesome in some individuals

Seborrhea is often described as being of two types The dry type, or so-called *seborrhea sicca,* is commonly known as *dandruff*. The oily type is the so-called *seborrhea oleosa* It frequently is impossible to differentiate the two types. Seborrhea

with acne vulgaris The eruption appears as dull reddish erythematous patches, often with greasy scales, often well defined on the body, and it sometimes forms annular lesions over the sternum Itching may not be very annoying except just before retiring and during the night The patient may awake to find himself scratch-

ing the scalp. Occasionally the dermatitis extends down from the scalp or f hairline to the forehead. The patch may be well defined at its borders.

Acne Vulgaris. The disease is manifested as an inflammatory affectioı sebaceous glands. The characteristic lesions, the comedo, the papule, and the are distributed over the face, trunk and buttocks, where the sebaceous gla largest The lesions are painless unless severely infected. In boys the lesior often on the nose and chin synchronously with puberty, and in girls with tl of menstruation

The primary infection has been attributed to *Bacillus acnes* (*Coryneba acnes*) It is secondary invasion of the lesions by staphylococci that leads to ן tion. The altered sebaceous secretion in the comedones turns black on expc air. When a comedo is expressed, a small plug or wormlike mass of material or shoots from the follicle to be followed by thin pus Around the papule : pustule is well-marked hyperemia. Sometimes the pustules increase greatly and furuncles develop Chronicity results in deep scars which, on the face, : as disfiguring as those of severe smallpox. If occlusion of the follicular oן takes place, sebaceous cysts develop.

Acne is differentiated from the drug eruptions by the history Iodides, br and various estrogenic preparations or hormones taken internally, and tar, ן and chlorine, when applied externally, may produce lesions almost ident acne, although not always on the usual sites.

After the patient has reached the age of 30 years, acne vulgaris tends gradually and the scarring is less conspicuous by the time the age of 40 y reached

Rosacea. The occurrence of rosacea about the time of the menopause, the menopausal flushing of the face, is etiologically suggestive of an enc association

Rosacea differs from acne vulgaris in the absence of comedones, in distr and in age of incidence. Often rosacea begins in the late twenties, or the ons be delayed until the forties It commences as a chronic hyperemia of the face often terminates in a permanent dilatation of the capillaries. During the co this hyperemia papules, pustules and a patchy scaliness occur The distribu the disease is on the nose, cheeks, chin and forehead, especially between the

Rhinophyma is the advanced or the extreme stage of rosacea. Its worst festations are seen in alcoholics. Often the rosacea is accompanied by an er ment of the tip of the nose, which becomes irregularly bulbous, forming fleshy mass pitted with dilated follicles from which sebaceous material c expressed The organism *Demodex folliculorum* found in these dilated follicl no etiologic significance

Senile Dermatoses. As age advances, the skin loses its elasticity, becom wrinkled, lusterless, and seems too big. Warts that resemble flat warts, but u are larger and have a dark surface, often appear over the neck and the trunk growths do not become malignant

Senile keratoses, little, hard, persistent areas of scaliness on the face, nos hands, are evidence of the effects on the skin from years of exposure to sui wind The skin of those who have red hair is more susceptible and more ser to these influences than skin of other coloration The extreme of sensitivity is s in xeroderma pigmentosum, and similar conditions may be produced by roe rays or radium in a much shorter time. They are of the same nature, however all have a tendency to become malignant

Hypothyroidism. Deficiency in thyroid secretion leads to decrease in the s tions of the skin glands, and produces a dry skin with increase in the thickne the horny layer (xeroderma).

These skin changes are improved by thyroid therapy. Hypothyroidism ma

occasion be accompanied by an ichthyosis. The ichthyosis too is improved by thyroid therapy. However, a deficient thyroid plays no part in the etiology of ichthyosis.

Skin Diabetes. Urbach has defined skin diabetes as the syndrome of therapy-resistant, recurrent or chronic dermatosis, a high fasting skin sugar level together with a normal blood sugar curve, and pronounced improvement of the skin disease, as well as a drop in the high skin sugar level, on a low carbohydrate diet, sometimes combined with insulin.

In support of this view that there is a connection between the clinical syndrome and a disturbance in the carbohydrate metabolism, as in diabetes, are (1) the high fasting skin sugar levels, which attain and even exceed 80 mg per 100 gm.; (2) the pathologic and characteristically diabetic course of the skin sugar curve following oral sugar feeding; (3) the return to normal of the fasting skin sugar level, as well as of the skin sugar tolerance curve after a low carbohydrate diet, notably in combination with insulin.

On the basis of clinical experience, a diabetic diet should be tried in cases of therapy-resistant skin diseases such as furunculosis, eczema or pruritus, even when the blood sugar tolerance curve is normal

THE EFFECTS OF DISTURBANCES OF NERVE FUNCTION OR PSYCHIC CONTROL

Pruritus. Pruritus is an integral part of the symptom complex of a great many skin disorders The cause of the pruritus may be an obvious organic disease or it may be entirely of functional origin.

Pruritus Ani vel Vulvae. Pruritus ani and pruritus vulvae are, in the large majority of cases, purely of functional origin Rarely will diabetes or threadworms (*Enterobius vermicularis*) be found as causative factors Occasionally a local condition, such as a vaginal discharge, hemorrhoids, anal fissure, or an intertrigo, will be found

Neurodermatitis. A neurodermatitis occurs as a well-defined patch of thickened, lichenified skin, often scaly, and intensely itchy, which has been present for a very long time. These lesions occur where they are easily accessible to the patient, and therefore can be frequently rubbed, or where the clothing rubs Irritation leads to itch and scratching, which increases the itch, and results finally in the thickened crisscrossed patch

Senile Pruritus. This general itchiness of the dry skin of elderly people may be a most distressing condition and may gravely alter their physical and mental well-being

SKIN DISEASES OF UNKNOWN ORIGIN

Psoriasis. Psoriasis is a common, not serious, dermatosis of white peoples The lesions occur more frequently and more profusely on parts of the body that are covered with clothing than on parts that are bare They do not cause the patient discomfort

Men are more often affected by the disease than are women, and morbid heredity seems to be of etiologic importance Some families are more prone to the disease than are others Lesions of psoriasis may occur along the line of a cut or scratch, in a scar, or on areas such as the waist where clothing presses. Apparently [illegible]

for years to a patch on the elbow or knee, and then suddenly it appears on other parts of the body The disease may be active while the patient is well and disappear during an illness such as pneumonia, or during a pregnancy, only to return when the patient regains his normal state of health. In some instances an acute exacerba-

tion may be activated by a general nervous debility. Remissions occur, the patient remaining free from the disease for years.

Sunlight is beneficial to most of these patients. The lesions may largely heal after repeated judicious exposure to sunlight. The natural dislike for exposing the affected ugly skin to view, however, prevents many of the patients from obtaining an adequate amount of sunlight.

The lesion of psoriasis is a reddish, *slightly thickened area of skin, covered to* a considerable depth with a glistening silvery scale. This character of the scale may not be apparent at first sight, but it appears if the lesion is scratched. As the scratching is continued, the scale gradually comes away in masses or as a fine powder until its lowest layer is reached. This layer comes away in one piece as a soft scale and leaves a red shiny area dotted with tiny bleeding points. Removing the scale as described is truly the *scratch* test and is almost diagnostic in doubtful cases.

The size and shape of the lesions of psoriasis vary. Descriptive terms are used for the variations, among which are the following. If the lesions appear acutely as profuse eruptions of small, distinct and irregular patches, the condition is *psoriasis guttata*. The spots may enlarge into sizable patches, as in *psoriasis nummularis*. If the scales become heaped up, the disease is of the rupial form, *psoriasis rupioides*. In some cases the center of the lesion clears while the edge remains active and circinate or serpiginous, *psoriasis circinata* and *psoriasis gyrata*. The size of the patch is roughly indicative of its age, and in some long-standing cases the patches may cover large areas of the body and limbs. They may have a maplike appearance, *psoriasis geographica*. In all cases, however, the scratch test indicates the nature of the disease.

The lesions usually occur on the extensor surfaces, and almost always the elbows and knees and the scalp are affected sites. On the scalp the hair prevents the scales from being easily shed, so that the disease in this area is more easily discovered by palpation. Lesions elsewhere usually will make the diagnosis of scalp lesions clear; the resemblance of psoriasis to seborrhea is not great. Psoriasis may be found behind the ears and under the breasts.

The nails may be affected, giving rise to irregular thickening of one or more nails. There may be rows of punctate depressions in the nails. In cases of psoriatic arthritis the lesions of the nails are sometimes the only ones present.

In rare instances exposed parts may be affected, and lesions may appear on the face and hands. Psoriasis of the palms and soles may assume a pustular *form*.

In some instances psoriasis appears to be associated with rheumatoid arthritis. Both psoriasis and rheumatoid arthritis are common diseases and some of the apparent association may be due to chance.

In doubtful cases differential diagnosis is made more easily if the scratch test is used repeatedly. Syphilitic lesions give a feeling of greater thickening of the skin, are more reddish brown than psoriatic lesions, and show involvement of the face and the forehead. Circinate psoriasis simulates ringworm but the scales do not contain fungus. Seborrheic pityriasis of the scalp may offer difficulty, the localized, heaped-up patches of psoriasis, palpable to the touch, and the scratch test help to differentiate the two conditions. Psoriasis of the palms resembles a ringworm infection and so may psoriasis of the nails, so that examination of scrapings for fungus [illegible]. Psoriasis and lichen planus may resemble each other.

[illegible] a lifetime. An acute attack may

[illegible]

The laity does not know that the disease is noncontagious. The patients should be discouraged from use of public swimming facilities and from military service.

Lichen (Rubor) Planus. Lichen (rubor) planus is a rare chronic, benign disease occurring in middle aged individuals which may persist for the rest of their lives. It can and does appear *in an acute form with a generalized eruption* which is accompanied by itching. It may disappear spontaneously after weeks or months. Women are more frequently affected than men. The general health remai[illegible]

Itching is not often severe though it may become severe enough to interfere with sleep. Oral lesions may be painful enough to interfere with eating.

The lesion is a polygonal, flat-topped, shiny, crisscrossed papule which breaks the fine lines of the skin The papule varies in size, sometimes reaching a few millimeters in diameter, but agglomerations of papules may spread over a large area. The light lavender color is characteristic of the lesions and may be observed at the edges of chronic patches if the scales are wetted away. A feature of the disease is the occurrence of the lesions along the lines of the ribs or places of skin trauma, for instance, where a belt or a corset or other clothing rubs the skin.

The general appearance of the lesion varies considerably. The acute lesions consist almost entirely of papules. Variations in secondary characteristics have occasioned descriptions of the following forms of the disease.

The *bullous* variety is an acute form characterized by bullae interspersed with the papules. The *annular* variety is characterized by rings of papules caused by the regression of the central lesions and the appearance of fresh papules in the periphery. The *hypertrophic* or *warty* variety is the characteristic manifestation of chronic lichen planus. This form may resemble psoriasis if the characteristic papules and violaceous color at the edges are not evident The *atrophic* variety is rare The patches are ill developed and the macular lesions are purplish or white, frequently striated, and sometimes surrounded by erythema

The mucous membranes of the mouth or the vagina may be affected, giving rise to leukoplakia-like lesions, especially if the tongue is involved These lesions of mucous membrane often cause considerable discomfort.

The flexor aspects of the forearms and the fronts of the legs and around the knees and over the sacrum are favorite sites of eruption. However, the eruption may be widespread, especially in acute attacks.

The disease may run a short course of a few weeks or months, and the patient gets well It is the chronic form, with chronic warty patches giving rise to discomfort by their presence on the legs, in the mouth or vagina or on the glans penis, which most frequently is seen by the physician

The essential lesions of lichen planus and psoriasis are different and the distribution varies in the two diseases In lichen planus the papules are on the front of the forearms, and often there are patches in the mouth In psoriasis the knees, elbows and scalp are involved Chronic scaly patches below the knees are found in both diseases, and if no lesions are present elsewhere, the diagnosis depends on local characteristics. Psoriatic patches have little or no itch and have a shiny scaliness which gives a positive reaction to the scratch test (p. 512). Chronic patches of lichen planus are itchy, in some cases intensely so, *the scale is not easily* removed, and the violet color is characteristic

A patch of neurodermatitis may simulate chronic lichen planus. A neurodermite may be very itchy, purplish or brown, with adherent scale and cross-hatched with lines, but its distribution is somewhat different from that of lichen planus The neurodermite is usually where it can be reached easily The papules typical of lichen planus are not present in the lesions of neurodermatitis or elsewhere on the body, and the violaceous halo of the lichen planus patch is absent.

The lesions of mucous membrane must be distinguished from leukoplakia. The lesions of the mucous membrane, especially of the penis, or of the skin may resemble syphilis

Pityriasis Rosea. This disease resembles a dermatitis due to an infection It is most prevalent in young adults. The herald patch, which has been considered the primary lesion, can be identified in about 3 of 4 cases. It often occurs on the lower part of the abdomen or on the flanks. The herald patch *appears before* the rest of the eruption and may pass unnoticed since it is usually symptomless It is distinguished by its greater size.

The essential lesion, including the herald patch, is an oval, rose pink macule

which enlarges and sheds fine scales as the center clears, leaving scales at the periphery. The long axis of the patches on the body is generally parallel to the line of the ribs The lesions may vary in average size and a papular form may occur. Vesiculation is a rare occurrence.

The herald patch is followed in 2 or 3 days, sometimes longer, by the general eruption which often is confined to the trunk and the upper parts of the limbs General symptoms are seldom evident, though an initial low fever may be present Usually the eruption fades and in from 4 to 6 weeks from the onset has disappeared, although it may persist for months. The eruption is not itchy One attack is thought to confer immunity

The ringed scaly lesions may suggest ringworm, but fungus is not present Seborrheic pityriasis and syphilis do not offer much difficulty in differentiation.

Pityriasis Rubra Pilaris. This rare condition is characterized by the appearance of reddish papules corresponding to the hair follicles over the limbs and face and the middle phalanges of the fingers Elsewhere the eruption may closely resemble psoriasis From psoriasis it is differentiated by the scratch test

Exfoliative Dermatitis (Pityriasis). An exfoliative dermatitis is characterized by redness and profuse scaling of the skin. It may occur secondary to many skin conditions, such as psoriasis, pityriasis rubra pilaris, drug intolerances, and poisoning by heavy metals such as organic arsenical compounds In a great many instances it is a reaction to overtreatment of a skin disorder The patient often is obviously ill The disease runs a chronic course.

The exfoliation is first manifest on intertriginous surfaces as the axillae or groins, and spreads quickly, so that the entire integument may become involved The skin is thickened and red, and there is profuse desquamation of large lamellar scales The degree of severity of the eruption varies considerably The desquamation becomes less In severe instances the eruption lasts for months and, especially in the elderly, the disease frequently is fatal

Indeterminate Vesicular Lesions of the Hands. *Cheiropompholyx.* Cheiropompholyx appears as minute vesicles, often discrete, on the hands, along the sides of the fingers and in the palms of the hands, and on the soles of the feet. The vesicles come to the surface of the palms and fingers, burst and leave a raw weeping surface which heals slowly, and thus may be subjected to much irritation which impedes healing. The slow healing requires that the condition be distinguished from *ringworm infection A differentiation from an infective dermatitis* (infectious eczematoid dermatitis) cannot usually be made

NEW GROWTHS

Benign Growths. *Callosities.* Callosities are thickenings of epithelium due to friction, heat, pressure, irritation and perspiration They may occur on any part of the body which is subjected to the foregoing forces The hands are favorite sites, for instance, the "horny hand of toil," but the callosities occur on the knees of the devout, on the buttocks of the lazy, and on the feet of those who walk a great deal

Callus and Corns (*Clavus*) As a rule corns are the result of pressure and friction from ill-fitting shoes which crowd the toes together and force them into a hammer-toe position. Hammer toe itself may be free of corns. Faulty foot posture [illegible] of weight stresses on certain areas of the foot is another causative [illegible] the interphalangeal joints cause clavus

As the horny layers of the corn become thickened, the apex is forced deeper into the sensitive papillae of the corium, and discomfort and pain result. Objectively there is a circumscribed callus, which when trimmed away reveals a horny mass extending as a cone downward into the deeper areas.

Soft Corns. Soft corns occur on the lateral surfaces of and in the web between the fourth and fifth toes, and the bony prominence is nearly always on the base of the first phalanx of the fourth toe. They do not become hard and dry but are soft and elastic because of moisture and maceration; for this reason, they are called *soft corns*.

Verruca Plantaris. Plantar warts are infectious in origin; and once infection has occurred, they tend to spread to other parts of the foot. Plantar warts apparently seldom occur except at the site of a callus

Plantar warts are small circumscribed callus-like growths which form on the plantar surface of the foot and about the heel They are extraordinarily sensitive to pressure and thus may produce discomfort seemingly out of all proportion to their size. Plantar warts differ materially from callosities and corns. Shave off the top of the horny callous layer of a plantar wart, and a central core, composed of hypertrophied papillae, which is soft and vascular and has a marked tendency to bleed, will be found.

Fibromas. In the majority of cases fibromas arise from sebaceous glands The most marked type is seen in the molluscum fibrosum pendulosum or fibroma molluscum (Recklinghausen's disease), which, when extensive, may cover most of the trunk with large pendulous growths, sometimes cystic, at other times like emptied sacks, at others like small cystic swellings. These are often called neurofibromas, which they are not.

Osteomas. Osteomas of the skin are often secondary ossifications and often originate from injuries, inflammatory processes or tumors In rare instances osteomas of the skin occur as congenital abnormalities.

Keloid. Keloid is an overgrowth of scarred tissue. It may have resulted from (1) an intense inflammatory reaction or (2) innate susceptibility peculiar to certain skins It is more nearly related to the texture of the skin than to the color. Keloids are likely to follow burns These growths often occur in operative scars, even small scars, and tend to extend beyond the limits of the original scars In the beginning there may be pain and tenderness on pressure. In time, a year or two, a keloid tends to disappear.

Xanthelasma (*Xanthoma*) Xanthelasma is a form of xanthoma characterized by soft, light leather-colored or yellowish patches appearing especially on the eyelids near the inner canthi (see Diseases of Cellular Lipid Metabolism in Chapter 22). These yellow nodules in the skin have no relation to diabetes (xanthoma diabeticorum).

Keratosis Senilis. Over the face, neck, back and hands of aging patients appear flat, moderately adherent, slightly raised, yellowish-brown to dark-gray or almost black lesions When forcibly removed they show horny prolongations on their under surfaces Some families who have freckles are more prone to have these lesions than are others Keratosis senilis has little or no tendency to undergo malignant changes.

Malignant Growths. Epithelioma. Epitheliomas *of the skin comprise (1)* the basal cell type (rodent ulcer) and (2) the prickle cell type (squamous epithelioma).

lioma and nevocarcinoma)

RODENT ULCER The rodent ulcer, basal cell carcinoma, is the commonest malignant tumor of the skin These lesions, usually multiple, (1) arise at the junction of skin and mucous membrane, (2) originate as cystic growths, benign at first, and (3) arise in elderly persons, beginning as senile hyperkeratosis The sites of occurrence are usually near the eyelids, nose, and about the ears, but the tumors may occur on any part of the face or hands. Generally there is a history of a lesion which commenced as a small papule and enlarged slowly over a period of many years, growing much more rapidly after ulceration set in In cases of long-standing ulcerat-

ing lesions about the face, the superior maxilla and the nose may become deeply eroded. In these regions the ulceration may, if not checked, often penetrate into the nasopharynx or up into the eyeball, causing great destruction in these regions.

Although rodent ulcer may affect children, the growth usually commences when the patient is about 45 years of age or older. When fully developed, the lesion is a small ulcer with an irregular base and a rounded edge with white firm nodules occurring along the margins of the ulcer. Superficial lesions may partly heal and scar over. No discomfort is present until the deeper tissues are affected, when there are severe pains

In some instances this skin lesion will have the features suggestive of syphilis, lupus and squamous epithelioma The history of syphilis is shorter than that of rodent ulcer, and as the disease generally is tertiary when ulceration is present, a search of the skin is made for the presence of other scars and pigmentation Serologic tests of the blood and spinal fluid may be made as aids to diagnosis Lupus generally commences before puberty, and while there may be scarring, the clear reddish nodules are commonly evident and do not possess the typical rolled edge observable in rodent ulcer. Squamous epithelioma is much more rapid in its growth than rodent ulcer and may be accompanied by secondary enlargement of the adjacent lymph nodes, which are not affected in rodent ulcer.

SQUAMOUS EPITHELIOMA Epithelioma in the early stage often leads to difficulty in diagnosis. It differs from rodent ulcer in being more rapid in its spread, in showing no healed areas, and in producing, in time, secondary involvement of the lymph nodes

In early stages differentiation between benign and malignant lesions and in later stages distinction between basal and squamous cell carcinoma, as well as the identification of rare tumors, can be made by biopsy study Biopsy in suspected skin cancer is simple and virtually harmless (except in the cutaneous surface, in mucous membranes and in the eye)

The prognosis depends on the size of the lesion and the adequacy of the treatment Small localized lesions without invasion, 1 cm. or less in diameter, are cured in 9 out of each 10 cases When lesions are 1 to 2 5 cm. in diameter, without deep infiltration, less than one half of five-year arrests may be expected Lesions more than 2.5 cm in diameter, with evidence of invasion of muscle, bone or cartilage, or with involvement of regional lymph nodes, are rarely curable, but significant palliation can usually be obtained through the use of protracted roentgen therapy, by means of electrocoagulation or actual cautery, or by other appropriate palliative surgical procedures However, some five-year arrests can be expected

Malignant Melanomas (*Moles and Pigmented Nevi*). Malignant melanomas may develop from pigmented moles of the skin as the result of trauma naturally occurring as from clothing, shaving, or tight fitting shoes, and trauma from incomplete removal A melanoma may become actively malignant during pregnancy. However, generally a quiescent melanoma or mole simply becomes malignant suddenly and metastasizes to distant parts.

When malignant change takes place, the mole may increase in size, become raised from the skin surface and may become deeply pigmented. It becomes inflamed, shows a moist surface, and bleeding may occur Sometimes a black spot appears in the mole. Occasionally a number of pigmented nodules develop around it The lesion becomes ulcerated, and, as the disease progresses, the regional lymph nodes become involved In some instances multiple widespread malignant lesions seem to occur simultaneously.

In some instances lesions similar to melanoma may be present These lesions are almost without color. If color is present, it is a light brown These lesions occur as very small flat nodules or as bulky tumors These lesions are in sharp contrast to the intensely colored ones which are of an intense bluish black to black.

There are no reliable criteria for differentiating between benign and early malignant melanomas. In general, the harmless lesions are more likely to be light in color and soft; they may be papillomatous, and may be hairy. Alteration, darkening in color, increase in size, change in contour or texture, arouses the suspicion of malignant activity. The appearance of satellite melanotic tumors about the periphery of the original lesion is evidence that dissemination has already occurred

Biopsy of pigmented lesions is definitely contraindicated. These lesions should either be widely and deeply excised or left alone It is impracticable and inadvisable to attempt removal of all pigmented nevi from all normal individuals. In general, lesions subject to frequent trauma situated on the feet, genitalia or conjunctiva and in which there is objective evidence of growth, inflammation or itching should be excised Once a malignant melanoma has become disseminated, only palliative measures are available. Melanomas are generally but not always radioresistant

Sarcoma. Sarcoma involving the skin, but seldom arising from it, occasionally is seen in nodular form occurring on various parts of the body. These tumors are highly malignant, as evidenced by rapid formation, reddish color, and tendency to ulcerate easily These growths may be recognized early, but not soon enough, for the prognosis, irrespective of treatment, is bad.

Kaposi's sarcoma occurs as multiple hemorrhagic purpuric-appearing lesions generally affecting the lower extremities of persons between the ages of 40 years and 50 years The course is variable but is less hazardous than that of the single sarcoma

Kaposi's sarcoma has to be differentiated from purpura hemorrhagica by a study of the blood for those findings diagnostic of purpura (see the Purpuras in Chapter 12). The diagnosis is made by histologic study of biopsied material

SUBCUTANEOUS TISSUES

Diseases of the subcutaneous tissue are usually considered with those of the skin or of the more deeply situated structures, for, interposed as these tissues are between the skin and more deeply lying structures, they may be affected in disease of either

The Reticuloses. The term reticuloses designates those conditions of the skin which may affect the subcutaneous tissues through involvement of the reticulo-endothelial cells of the skin and the lymph nodes.

The reticuloses include the leukemias, the lymphoblastomas (Hodgkin's disease), mycosis fungoides and lipolemic reticulosis In the leukemias and the lymphoblastomas there occasionally are lesions of the skin, whereas in mycosis fungoides the skin manifestations are the characteristic feature of the disease.

In the reticuloses granulomatous lesions are relatively rare in the skin It appears that in the initial states the tissue reaction in the skin is more acute in type than that in the lymph nodes However, fibrosis and the development of Sternberg-Reed cells are seldom exhibited in the skin Lymph nodes, therefore, are far more promising leads toward histologic diagnosis than the skin. The eosinophilia in some cases may or may not be significant of an interrelationship with eosinophilic granuloma.

The cutaneous lesions, when present, in lymphatic leukemia and lymphadenoma consist of pruritus, urticaria, or a nodular, purple or reddish brown eruption A general exfoliative dermatitis may occur, especially in Hodgkin's disease. The diagnosis can be made only from histologic studies of sections of the affected skin.

Lipolemic Reticulosis. Lipolemic reticulosis may resemble Hodgkin's disease and other reticuloses The histologic changes in the lymph nodes are constant. There is disorganization of the normal structure of the nodes, though this is usually spotty In those areas the lymph sinuses are dilated, and often empty. There is proliferation of the reticular tissue, and many eosinophils and histiocytes are present Melanin is

present in large amounts, both free and in melanophores. Fat stains show considerable lipoid material

The usual clinical manifestation is a generalized lichenified or eczematous eruption of several years' duration, with darkening of the skin. In Negroes there may be depigmentation. Often there is loss of hair, especially of the scalp and axillae. Frequently there are changes in the nails, with thickening and discoloration and subungual thickening and hyperkeratosis.

Lipomas. Lipomas occur as lobulated or rounded masses in the subcutaneous tissue. They are soft and freely movable. When traction is made on the overlying skin, multiple small dimples form in it. Hard lipomas are designated fibrolipomas, whereas those having an increased vascularity may be called angiolipomas.

These tumors may occur anywhere in the body but are most commonly situated in the subcutaneous tissues over the back, shoulders, neck, thorax, abdomen and buttocks and legs. Other sites for lipomas are the mesentery, and serous tissues of the whole alimentary tract, kidneys, heart, uterus, meninges, respiratory passages and occasionally in the mouth and tongue

Lipomatosis. Multiple localized or unusual depositions of fat are classified as lipomatosis to distinguish them from the single localized fatty tumors and form of obesity. They cause little concern except from a cosmetic point of view or when they mechanically interfere with normal function because of being inopportunely situated so that function may be disturbed.

Heredity is an etiologic factor in the symptomatic progressive forms of lipomatosis. Lipomatosis of the pseudohypertrophic form of muscular dystrophy in which the adipose tissue invades between the muscle bundles causes some of the abnormal enlargement of the legs in these children. Lipodystrophia progressiva, a rare condition of girl children, is characterized by complete disappearance of subcutaneous fat above the hips and the development of psychoneurotic symptoms. In the nodular circumscribed lipomatosis the lesions are distributed as firm, discrete, freely movable subcutaneous tumors over the forearms, thighs and often the back. The diagnosis is usually obvious, but a biopsy study may be necessary for confirmation.

Adiposis Dolorosa (Dercum's Disease) Dercum's disease, or adiposis dolorosa, is a syndrome consisting of tender and painful fat nodules, often attaining large size, situated in the femoral and inguinal regions or in the cervical region. When the nodules are situated over smooth surfaces, the skin may become erythematous and stretched and tender. The patients are often partially disabled by weakness and apprehension

The disease is not an established entity in regard to etiology or pathology. It may last a long time, and during this time there is a gradual increase in deposits of fat and in the accompanying discomforts.

Fibromas. A fibroma is a circumscribed purposeless arrangement of fibrous cells. Fibromas are variable in size and consistency, some are soft and loose in texture, others are firm and hard to the palpating hand.
